Fig. 18. An example of slitting preliminary to bending a tab, and an example of lancing to produce either a ventilating louver or a locating projection.

TRIMMING is the operation of cutting off the excess stock provided for forming operations where it is difficult to predict the exact nature and extent of the metal flow. There are three variations of this operation known as conventional trimming, pinch trimming, and lateral or cam trimming. Conventional trimming is used after drawing or other forming operations which leave a flange on the perimeter of the part. Conventional trimming also leaves a flange but cuts off the excess metal so as to create the desired size and shape of the perimeter. Pinch trimming is used to cut off all the flange remaining on the formed or drawn parts, but it leaves a sharp ragged edge. Where it is necessary to remove the flange a better job can be done by using conventional trimming, leaving a flange equal to three or four times the stock thickness in width and following up with a drawing operation. When the latter procedure is either inadvisable or not feasible, then lateral or cam trimming may be used. In this instance the part is usually mounted on a suitable locating punch and then driven laterally by cams for the cutting phase of the operation. This usually calls for relatively expensive dies and is used only as a last resort for continuing large quantity production. Conventional trimming and lateral or cam trimming can be performed with the same degree of accuracy as blanking. Pinch trimming usually creates greater variations in the length or diameter of the part; it is more pronounced with the softer and thicker metals.

SHAVING is a follow-up operation for increasing the accuracy of surfaces or edges which have been cut by blanking, punching, notching, shearing, and other so-called first operations. Shaving is usually performed as a single operation, although it may be divided into several steps where extreme accuracy is required. Where careful control is exercised it is possible to control dimensions within 0.0002 in. by shaving. A typical shaving cut on the perimeter of a part removes a chip equal in thickness to about 15% of the stock thickness. The punches and dies are usually constructed with zero clearance, and the parts to be shaved must be located as accurately as possible. Shaving cuts less than 0.005 in. thick should not be attempted on stainless steel and other metals which work-harden severely.

BROACHING can be defined as internal shaving since its purpose as an operation is to improve the accuracy of pierced holes. Broaching cutters often have more than one cutting edge and can be used in stamping presses to produce the final size of holes in castings and forgings as well as in stampings. If the broaching tool is constructed with more than one cutting edge the pitch should be such as to maintain at least one cutting edge in contact with the work piece at all times during the cut.

DINKING is an operation similar to blanking and shearing used to cut novelty items from paper, leather, plastics, and similar materials. The lower half of a dinking die usually consists of a plain flat plate or board, and the upper half consists of a plate on which strip tool steel is mounted on edge with the opposite edge ground to a knife edge. A typical application of this operation is in the making of jigsaw puzzles from lithographed cardboard.

BURRING, like lancing, is a combined operation involving both cutting and forming. In its simplest form a bullet-nosed punch is forced into the sheet metal causing it to rupture and bend out the opposite side. The purpose of this operation is to raise a boss on the sheet metal to provide greater bearing area for a screw or a rivet used to fasten the part to another part. There are several other variations of the burring operation, one of which is illustrated in Fig. 19. In this method a hole is first pierced from one side and then a larger-diameter bullet-nosed punch is forced through from the other side of the sheet, thus raising a crude boss. The height of a boss which can be raised by this method is usually limited to about two times the stock thickness. Bosses of greater height can be created by first drawing a shallow cup and then piercing out the bottom of the cup.

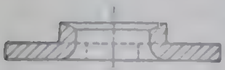

FIG. 19. A raised boss or burr as produced by the burring operation; the dashed lines show the hole pierced prior to forming.

BENDING. The usual connotation of bending applies to the operation as it is performed in the stamping process. It always involves bending the metal about a straight-line axis rather than a curved axis. The extent of a bend is designated by the included angle after bending and the sharpness is designated by the radius at the inner corner. Some grades of aluminum and brass can be bent to a zero radius. Other materials possess low ductility at bending speeds and require substantial radii at the inner corner to prevent rupture of the metal. For example, a hard rolled magnesium alloy requires a minimum radius of seventeen times the thickness of the stock for a 90-degree bend. Most metals can be bent successfully with a minimum radius of three times the stock thickness. The design of a part to be produced by stamping should include as large bending radii as possible. When bend radii must be held to a minimum it is advisable to consider selecting material suitable for this purpose. With strip material which is rolled only in the longitudinal direction, a bend can be more severe when the axis is across the direction of rolling than when it is parallel to the direction of rolling. When a part contains critical bends with axes at 90 degrees to each other it may be necessary to use sheet stock which has been rolled in both directions.

It is more economical to specify a generous tolerance on the angle of bend in view of the spring-back inherent in the bending process. The amount of spring-back is greater with large bend radii. It is possible to minimize the amount of spring-back for a given bend through proper design of the bending die. Figure 20 shows two simple bends, the first a V bend and the second a U or channel bend. In the first instance it is possible to strike the metal in the corner at the bottom of the stroke, thus extending more of the stressed fibers through the yield point, creating more permanent set, and thereby reducing the amount of spring-back. This cannot be done readily with the channel type of bend unless the bending punch can be made to approach the corner at a substantial angle from both sides. Therefore, where spring-back must be controlled, it is advisable to design the part to permit bending in a V die.

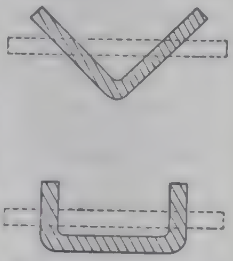

FIG. 20. Bending in a V-die permits striking in the corner to overcome springback; making a U or channel bend usually requires overbending to offset the effects of springback.

SEAMING is in reality a bending operation with a unique application. It is used for joining the ends of a strip of sheet metal in the making of cans, containers, etc. Three stages of a simple seaming operation are illustrated in Fig. 21. The same limitations peculiar to bending are also applicable to the seaming operations.

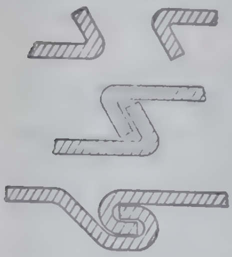

FIG. 21. A series of steps for producing a locked joint by seaming.

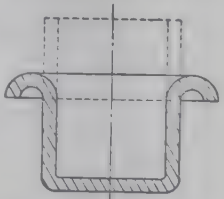

FIG. 22. A curling operation used to produce a rim at the open end of a drawn part; the rim can also be curled inward.

CURLING is the operation of rolling over the sharp edge of a drawn part. It differs from bending in that the axis of the bend is a curved line. Figure 22 shows a typical curling operation in the forming of a rim around the top of a drawn cup. The upper edge or rim of the cup could be curled inward as well as outward. The general limitations applying to bend radii and bending also apply in curling; however, there are additional limitations arising from the curved bend axis. For example, in curling the rim of the cup illustrated in Fig. 22, the metal is not only bent but it is also stretched in a peripheral direction. The tensile stresses created by the stretching are superimposed upon the tensile stresses set up in bending; therefore, the minimum bend radii are larger than for the corresponding bending operations with the same material. Most materials which can be deep drawn can be curled easily with a minimum radius of five to six times the stock thickness.

STAMPING is a shallow forming operation involving no substantial changes in the thickness of the metal. It is used to produce decorative configurations, lettering, and beads intended to increase rigidity of otherwise plain areas by increasing the section inertia. The word stamping is now used to describe all operations performed on the sheet metal in mechanical and hydraulic presses. In the early stages of development of sheet metal operations drop hammers were used to produce lettering and decorative configurations; that is why the name stamping is still used in connection with these operations. At present, most stamping operations are performed in mechanical crank-type presses or in hydraulic presses. The name impact stamping is applied to all operations performed on sheet metal by dies operated in either drop hammers or air hammers. Impact stamping is discussed in Article 9. Figure 23 shows a typical arrangement of the tools and work for a stamping operation. The metal is stretched to produce the bead; there is some flow of metal from the adjacent regions into the bead. The height of a bead or letter is usually restricted to no more than ten times the metal thickness, and it is considered good practice to make the width of the bead at least equal to its height.

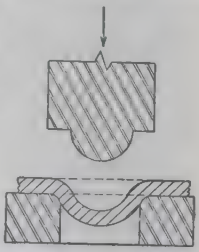

FIG. 23. The forming of a bead, letter, or decorative configuration by stamping or shallow drawing.

CONVENTIONAL DRAWING is illustrated in Fig. 24. It is called conventional drawing because it is the method used most frequently for producing cups in small and medium sizes. The cups can be drawn with or without a flange and in almost any desired cross section. The metal blank is permitted to flow toward the die cavity without any constraint other than against buckling. Internal resistance to flow of the metal toward the punch and die sets up compressive stresses which, combined with tensile stresses created by the motion of the punch, give two-dimensional shear. This is a very desirable internal-stress condition which requires a minimum of applied force to form the metal.

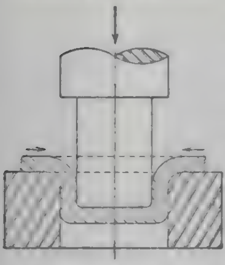

FIG. 24. An example of conventional drawing.

In the simple case of drawing a cylindrical cup from a circular blank the operation is limited theoretically to a reduction of 50% in diameter from the blank to the cup. If a greater reduction is attempted the tensile stresses will be greater than the compressive stresses at the start of the draw, and the bottom of the cup will be torn out by the punch. Further consideration of work hardening, friction, and superimposed bending stresses makes it advisable to attempt substantially less than a 50% reduction in diameter by this process. A conservative rule to follow is one which limits successive reductions in diameter or overall dimension to two-thirds of the per cent elongation of the material as obtained from standard tensile tests. The radii at the corner of the punch and die should be at least as great as the minimum established for bending the same material. The procedure for determining the number of successive draws and redraws that can be obtained prior to annealing is demonstrated in Examples 1 and 2 in Article 5.

REDUCING is illustrated in Fig. 25. It is used most often in the production of containers where it is necessary to produce a neck. Consequently, the operation also is referred to as necking. The metal in a previously drawn part is made to flow in compression, thus reducing the diameter locally. Since the sheet metal is compressed, it is subject to buckling or wrinkling in a circumferential direction; this makes it necessary to limit the amount of attempted reduction in a single stage. The amount of reduction that can be accomplished without wrinkling is a function of the thickness of the metal, the friction between the die and the metal, and the included angle of the conical portion connecting the neck with the main body of the container. The commercial range of reduction by this operation varies from 5 to 20%; the lower values should be used for relatively thin-walled material in the work-hardened state and when the included angle of the conical portion approaches 90%. The higher values can be obtained when the wall thickness is relatively great, when the metal work-hardens slowly, and when the included angle of the conical portion is relatively small. When the included angle of the conical portion exceeds 90 degrees it is advisable to bulge the part rather than to attempt necking or reducing.

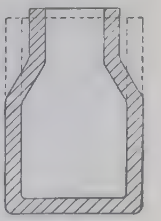

FIG. 25. An example of reducing to produce a neck on a container. The operation is similar to the drawing of seamless tubing except that the part is pushed into rather than pulled through the drawing die.

BULGING is illustrated in Fig. 26. This operation is usually applied to previously drawn cups. It can be accomplished in mechanical dies with either segmental steel punches or with rubber when the punch can be made to collapse sufficiently to permit entry and removal through the neck. More extensive bulging can be accomplished with hydraulic dies wherein a fluid medium such as water is compressed by a punch entering the neck, thereby stretching the metal out against the surfaces of the constraining die. The height of the cup will be decreased during the bulging operation because of unpredictable variations of friction and flow characteristics of the metal. It is therefore necessary to provide some excess height in the drawn cup and to obtain final height of the bulged part by trimming, curling, or some similar operation.

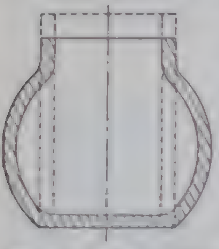

FIG. 26. Bulging, which stretches the metal, is resorted to when the inverse operation reducing either is too expensive or cannot be performed because of the danger of buckling.

STRETCH DRAWING is the name applied to the forming of such parts as automobile doors, body panels, and tops from large sheets of metal. The metal is relatively thin in proportion to the total area involved and would wrinkle badly if drawn in a conventional manner. Therefore the edges of the sheet or blank are constrained in varying degrees to induce a predominance of tensile stress, thereby preventing buckling or wrinkling. Friction plays a very prominent part in this operation and practically controls the severity of stress in any particular region. Consequently, details of the die as well as the shape of the part must be developed by cut-and-try methods. It is not unusual in the automotive industry to allow as much as a year for the design, construction, and try-out of large dies for stretch drawing.

An oversimplified arrangement of the material and tools for stretch drawing is illustrated in Fig. 27. The pressure ring surrounding the punch is used to constrain the sheet metal around its perimeter. A series of beads and depressions on the surface of the die and within the pressure ring increase the grip on the perimeter of the stock. By varying the height and number of the beads, it is possible to control the amount of flow of the metal toward the punch, thus permitting sufficient flow to prevent tearing and yet restraining the flow sufficiently to prevent wrinkling. Since friction plays such a prominent role, lubrication and surface roughness of the punch and die elements are very important and require competent consideration.

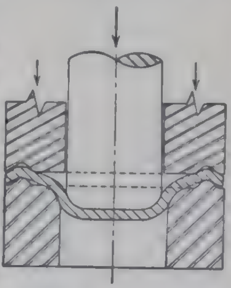

FIG. 27. Stretch drawing requires a firm grip on the perimeter of the blank to retard the inward flow of the relatively thin metal; unrestrained flow would result in serious wrinkling. This method is used to produce automotive body panels and similar large stampings.

IRONING is an operation used to increase the depth of previously drawn cups by thinning out the side wall as illustrated in Fig. 28. This operation is usually divided into several steps wherein the diameter of the punch is maintained constant and is used with a series of progressively smaller die rings. It is very similar to the drawing of seamless tubing in that the cup is literally pulled through the die. The same operating conditions that are used for drawing tubing must also be used for ironing. The principal difference is related to the fact that the main objective of ironing is to lengthen the part by thinning out the walls, whereas in tube drawing the principal objective is to reduce diameter.

Ironing is particularly adapted to the manufacture of cartridge cases from previously drawn cups. Brass is most suitable for this operation although steel has been used successfully in recent years. Application of the process is limited only by economic considerations. The long stroke required for deep cups calls for large, expensive, and slow operating presses, and frequent annealing adds considerably to the cost of processing. The maximum reduction in wall thickness which should be attempted in the first stage with a 70 : 30 brass is 45%. This should be tapered off to about 30% in the last stage, provided it is to be followed by a reducing or necking operation. The procedure outlined in Fig. 15 can be used to determine the extent of reduction of wall thickness prior to annealing.

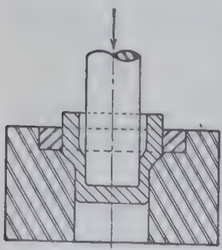

FIG. 28. Ironing is used to lengthen tubular parts by thinning out the side wall.

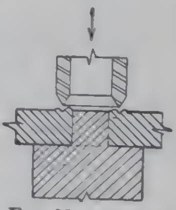

FIG. 29. Staking, the inverse of riveting, is used for fastening one part to another by deforming or peening the metal surrounding the stud or rivet.

STAKING is a press operation used for assembly of component parts. It is somewhat the inverse of a riveting operation as illustrated in Fig. 29. A hollow punch, the rim of which is ground to a sharp edge like that on a cold chisel, is forced into the metal adjacent to the hole, thus peening it against the shaft or stud placed in the hole. The staking punch creates compressive stresses generally near the surface of the work while at the same time causing very high tensile stresses locally at the sharp edge; this causes permanent set in the region of the tensile stress, thus leaving residual compression when the punch is removed. The stud or shaft can be serrated or knurled to increase its torque capacity. This method is used extensively for fastening brass, aluminum, and zinc parts to other parts which can be made of any metal.

SIZING is literally a cold-forging operation used to produce the desired size of a forging or sheet metal assembly by squeezing it between constraining punch and die elements. It is necessary that the metal be stressed thoroughly in compression so that it will hold its shape through permanent set. Application of the operation is restricted to relatively simple shapes for which rigid die elements can be made to apply considerable force over the entire areas concerned. A typical application of this operation is in the production of the desired contour of an automotive brake shoe which has been assembled by riveting and spot welding from several sheet metal components. This operation is occasionally referred to erroneously as "coining," in which the metal is constrained against flow in all directions.

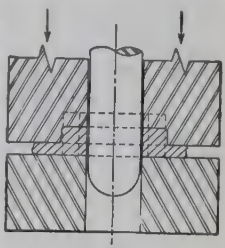

FIG. 30. An example of cold forging a part by swaging in an open die; the dashed lines indicate the original shape of the prepared blank. The perimeter of the swaged part must be trimmed to final shape and size.

SWAGING begins with a relatively thick blank which is squeezed in compression between a punch and die causing the metal to flow outward through the diminishing orifice between the punch and die. Figure 30 shows a typical arrangement of tools for producing a small wheel or gear blank with an integral hub by this method. Almost any metal can be swaged although it is obvious that the extent of the change in shape can be greater with metal possessing a high ductility. Brass, aluminum, or zinc are usually selected for this purpose. The metal will not flow out through the orifice in a uniform wave front; therefore it is necessary to use an excess of material so that trimming or trimming and shaving can produce a final size and shape of the perimeter. The shape and size of the blank should be such that the metal on the perimeter of the part will be stretched no more than the corresponding per cent elongation obtained from standard tensile tests, and the reduction in thickness should be kept within the working range of the material as given in a chart similar to Fig. 14 or Fig. 15.

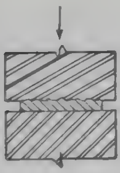

FIG. 31. Schematic sketch of an embossing operation wherein the desired configuration is produced without bending; the metal is free to flow outwardly between the two halves of the die.

EMBOSSING is the act of producing a desired configuration on one side of a piece of sheet metal without any corresponding change in the surface of the other side. This operation is illustrated schematically in Fig. 31, wherein the desired configuration is machined into the upper die block while the lower die remains flat. The metal is not constrained on the perimeter of the part being embossed. This operation is used to produce lettering and decorative configurations on the surfaces of such soft ductile metals as brass and aluminum. The amount of metal movement is slight, but the sharpness of reproduced detail and the life of the die are increased by the selection of a relatively soft ductile metal.

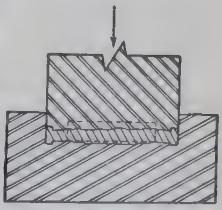

FIG. 32. Coining is similar to embossing except that the metal is constrained within a positive die which determines the outside dimensions and may be used to produce serrations on the perimeter.

COINING is very similar to embossing in that it is used to produce shallow configurations, but in addition the metal is constrained against lateral flow through the use of a positive punch and die arrangement as illustrated in Fig. 32. Thus serrations can be produced on the perimeter of the coin. Only relatively soft materials or alloys are selected for processing by this method; such alloys are gold, silver, copper, aluminum, brass, etc.

EXTRUDING produces the most severe metal flow of all the stamping operations. It involves squeezing the metal through an orifice by the application of pressure with a punch. There are two variations of this process in general use. The first variation, which might be called conventional extruding, begins with placing a blank of the material to be extruded in a closed die and applying pressure with a punch. The metal is extruded through the clearance space between the punch and die cavity and moves upward around the shank of the punch. This is the method used for making toothpaste tubes and other containers of this type. The bottom of the die cavity can be given almost any shape that may be desired on the end of the extruded tube. The metal does not extrude with a uniform wave front, and therefore it is necessary to use an excess of metal, making it possible to trim the extruded part to the desired length.

The other method of extruding is known as the Hooker process. In this process the die opening extends down through the die block, and the extruding orifice is created by the clearance space between the punch and the wall of the die. Pressure is applied by a shoulder on the punch which forces the metal to be extruded downward. The extruded part remains in the die when the punch is removed, and it is necessary to follow up with another punch to pinch out the excess material and push the completed part the remainder of the distance through the die. Products made by this process are frequently referred to as Hooker tubing. Various preliminary steps may be required in preparing the blank for this process, but it is relatively fast and the necessary trimming has been accomplished by the time the part leaves the die. Lead, tin, and soft grades of aluminum are most often selected for parts to be made by extrusion in stamping presses. Copper, brass, and zinc may also be extruded successfully. A large variety of containers is manufactured by this process, and much development work has been done by the materials suppliers who are usually eager to pass on the benefits of their development work. The process is used only for very large-quantity continuing production since some development is usually required for each new shape and size of part.

7. CHARACTERISTICS AND APPLICATIONS OF DIES

Most of the stamping or press operations can be grouped two or more to a single set of tools or stamping dies. Consequently, several operations can be performed simultaneously or in sequence within the same stamping press. The various ways in which the operations can be grouped impart unique characteristics and possess certain advantages and limitations which should be taken into consideration during the earlier steps of production planning. Most stamping dies can be included in one or more of the following classifications: (1) simple, (2) compound, (3) combination, (4) progressive, (5) transfer, and (6) special.

SIMPLE DIES are those intended to perform but one operation. That operation may be either the cutting type or the forming type. As the name implies, this type of die is usually of the simplest possible arrangement and construction consistent with the intended quality of product and life of the die. These dies vary in quality, complexity of design, and cost from very simple cheap dies for small production runs to very elaborate well-engineered expensive dies for large-quantity continuing production.

COMPOUND DIES are single-stage dies for performing two or more operations of the same general type. For example, a compound blanking and piercing die wherein two cutting operations are performed or a compound drawing and embossing die wherein two forming operations are performed. The several operations may be performed simultaneously or in sequence. The most important characteristic of this die is that all the operations are performed on the part in one location. Consequently, stamped parts can be produced within relatively close limits since the dimensions between component elements are controlled by the degree of precision achieved during the construction of the die. The principal disadvantage of this type of die is that the die elements are often crowded very close together. As a result of the crowding, they may be relatively delicate and will require slower operating speeds and greater maintenance.

COMBINATION DIES are single-stage stamping dies performing operations from both the cutting and the forming groups. These dies possess the same general characteristics as the compound dies discussed previously.

PROGRESSIVE DIES are multiple-stage dies in which two or more operations are performed during the same stroke of the press, but at several work stations. The work is fed progressively through several stages, and one or more operations may be performed at each stage. A progressive die actually may consist of several simple dies mounted on common supporting elements. Some progressive dies incorporate combination and compound as well as simple stages. However, the primary objective of the progressive-die arrangement is to achieve greater rigidity and simplicity as compared with compound and combination dies, consequently permitting increased operating speeds in addition to reducing maintenance and construction costs.

Progressive dies are normally used to process continuous strip or coil stock which is mounted on reels and fed by automatic feeding equipment during a predetermined interval of the press stroke. This permits the use of automatic presses for continuous operation. The part or blank is left integral with the strip until the last stage, where it is removed. Since the strip is used to transfer the part from one stage to the next the tolerances on location of part details must be at least as large as the expected error in feeding the strip. Consequently, parts made in progressive dies may not be as accurate as those made in simple dies, compound dies, or combination dies.

TRANSFER DIES possess many of the characteristics of progressive dies since they also contain multiple stages. Some parts, because of complexity or large size, cannot be processed readily in a progressive die because the strip cannot be used to feed the part from one stage to the next. Transfer dies can be used for these parts because they incorporate a transfer mechanism for moving the part. The transfer mechanism may be radically different for each new part; therefore, it is usually considered as a part of the die rather than as standardized press equipment.

Transfer dies are usually more expensive than progressive dies because of their greater size and the additional cost of the transfer mechanism. They are not as common as progressive dies because large and complex parts are not made as often or in as large quantities as the smaller and simpler parts. Transfer dies are used only for large-quantity continuing production. Compared with simple, compound, and combination dies, they will operate at higher production rates with lower maintenance cost and longer life. However, they may require wider tolerances on the relative location of component elements.

SPECIAL DIES are those whose design and functions are so radical that they possess none of the dominant characteristics of the more general classes of dies. Typical of dies which can be classified in this group are lateral trimming dies, hydraulic dies, universal dies, and rubber dies.

Lateral Trimming Dies. Occasionally a part, like a cylindrical cup without a flange, must be trimmed to length. The trimming can be done in a stamping press with an unorthodox die incorporating a sequence of lateral motions. A patented variation of this type of die is known as a Brehm die.

Hydraulic Dies. A hydraulic medium like oil or water can be used with a die for bulging or expanding parts which can be made to contain a fluid during the operation. This type of die is particularly useful in the manufacture of musical instruments and several types of containers.

Standard or universal dies are usually very simple in design and possess certain universal characteristics which permit them to be used for a range of sizes or different types of operations. These dies are basically simple dies intended to perform single operations, but they are designed so that punch and die elements can be quickly adjusted to new locations or replaced with different sizes. This makes it economical to use stamping for producing as few as thirty to fifty parts. There are many different design variations in universal dies, and some of the more useful types can be purchased as standard catalog items.

Rubber dies, as used extensively by the aircraft industry, are similar to universal dies in that they are well adapted to the production of relatively few parts. In addition they possess certain advantages for the forming of aluminum and magnesium alloys. These dies and their application are discussed in greater detail in Article 9 under the heading of Unique Process Variations.

8. SELECTION OF PRESSES

The selection of a press for the performance of stamping operations is based on the type of press and the peculiar characteristics which make it adaptable for certain purposes; the size of the press as to platen and bed area, bed opening, size of bolster plate, length of stroke, etc.; the force or tonnage capacity both at midstroke and near the bottom of the stroke; the work or energy capacity; and, finally, the electric motor for driving the press. The catalogs and engineering bulletins of press manufacturers should be consulted whenever available. The Automotive Joint Industry Conference in cooperation with press manufacturers and other suppliers has developed standards on presses, bolster plates, and other pressroom equipment. When they are adopted more generally, these standards will do much to simplify the problems of equipment selection.

The three basic types of machines used for metal stamping operations are hammers, hydraulic presses, and mechanical presses.

HAMMERS were used rather extensively during the early history of the development of metal stamping. Board-lift and steam hammers are used almost exclusively for forging operations. Rope-lift hammers have been used to some extent in the aircraft industry, although the faster and more versatile air hammers are finding increasing favor in this field.

HYDRAULIC PRESSES are built in sizes varying from small $^3/_4$ ton bench-type presses up to huge 15,000-ton four-post presses. Unlike mechanical presses, the rated force or tonnage capacity is available over the entire length of stroke. The available operating stroke of hydraulic presses is also substantially longer than the corresponding size of mechanical press. Most hydraulic presses are essentially slow-moving machines because of the limitations of pumping equipment in handling the large quantities of oil necessary to fill relatively large cylinders. However, the relatively recent development of rapid-traverse circuits has expanded the economical applications of hydraulic presses to the point where they are being used very successfully on many competitive high-production, deep-drawing jobs. They have also found extensive use in the aircraft industry in connection with rubber dies. (See Article 9.) Small and medium-sized hydraulic presses are usually built with square platens varying in dimension from about 8 in. square on up to several feet on a side. The larger presses are usually custom built to the customer's specifications. A high-speed hydraulic stamping press has recently become available on the market. This press with a maximum capacity of 50 tons can operate with a 4-in. stroke up to 100 strokes per minute.

MECHANICAL PRESSES may be classified in several ways on the basis of the construction of the frame, the mechanism for providing motion to the ram, and whether or not it is provided with the auxiliaries required by an automatic press. On the basis of frame design, the presses are classified as gap or C frame, arch type, straight side, and pillar presses. Most of the presses in the small and medium sizes may be mounted in a vertical position or in a tilted or even horizontal position to facilitate stock removal. Motion to the ram may be provided by cranks, eccentrics, cams, toggles, screws, knuckle joints, and in one instance by a Scotch crosshead. Mechanical presses are also classified as single-action, double-action, or triple-action presses in which case reference is made to the number of moving slides or rams. Double-action presses consist of an inner ram contained within an outer ram, while triple-action presses have the added facility of a third slide operating from the bottom of the press.

Gap or C-frame presses are constructed in a wide range of sizes from very small bench presses up through the medium-sized range. They are available in many design variations, making them adaptable to a very broad range of application. They may be equipped with automatic indexing dial feeds for assembly work and for performing a number of operations in sequence on simple parts. They may also be obtained with the crankshaft running from front to back and with or without a solid steel arm or horn extending from the frame for folding or seaming operations. This type of press is usually available only as a single-action press, but it can be used for every type of stamping operation except those which require long stroke, large bed area, or exceptional force capacity.

The press brake, a special variation of the gap-type press, has been developed particularly for making long bends. Relatively complex shapes can be bent from long stock with relatively simple dies. These presses are particularly useful in aircraft, bus, railroad, and similar fields where long structural parts must be fabricated from sheet metal.

The arch type of frame is not used very extensively except in percussion presses. These are power screw presses which occupy an intermediate position between hammers and the relatively high-speed mechanical presses. The slide is driven by a large steep-pitched screw, operating through a fixed nut in the frame and a light flywheel on top. Friction contact at the flywheel rim with the constantly revolving disk on one side drives the slide at increasing velocity until the die comes in contact with the work and all the energy stored in the flywheel is absorbed. Then another revolving disk makes contact with the other edge of the wheel and lifts the slide. Foot treadle control, similar to that of a drop hammer, is used. This press is very well adapted to slow-speed squeezing operations where it is desirable for the operator to exercise some control over the process by varying the speed of application and the magnitude of the applied force. The press is useful for hot press forging and for such critical operations as the pressing of sintered carbide wire drawing dies into alloy steel holders.

Straight-side presses along with gap presses represent the major proportion of all mechanical presses in use. They are built in medium sizes as well as in the very large sizes. The single-action presses of this type are available with force applications to the ram at one, two, or four points, depending on whether one, two, or four cranks or eccentrics are used. The number of points of force application to the ram increases with the size of the press. Single-action presses of this type are built in sizes large enough for stretch drawing of automotive turret tops and floor panels. In this case the punch is mounted on the bolster plate, and the pressure or holding ring contacts a series of air cushions by means of pins through holes in the bolster plate. Single-action straight-side presses are being used more and more for stretch drawing of very large parts.

Double-action presses are usually of the straight-side type. They are intended for drawing operations wherein the outer ram can be used for blank holding while the inner ram carries the punch. The outer ram must precede the punch to the work and grip the blank firmly, holding it during the entire working stroke of the drawing punch. The inner ram which carries the forming punch is operated by one or more cranks in all double-action presses. The outer ram is usually operated by cams in the smaller double-action presses. A toggle linkage is used to actuate the ram in the larger sizes. These linkages are usually compounded and are driven by a crank on the end of the crankshaft through long pitmans and crossheads which permit the entire linkage to act like a huge spring, thus maintaining the pressure ring in contact with the blank during a large fraction of the revolution of the crankshaft. These so-called toggle presses are used extensively for stretch drawing of large parts.

Knuckle-joint presses are in reality toggle presses since a single toggle linkage is used to actuate the ram. These presses combine long stroke with considerable force capacity and are used for ironing, swaging, embossing, coining, and similar operations of the squeezing group which require very high force capacity.

Automatic presses are available in many types. These presses are intended for completely automatic and continuous operation rather than for intermittent operation by the press operator. They are usually equipped with automatic feeding devices, scrap cutters, safety limit switches, and similar auxiliaries. Some gap-type presses are so equipped although most automatic presses are basically of the straight-side design.

There are some special automatic presses which differ radically in design from those discussed previously. One of these marketed with the name Super-Speed Press uses the principle of the Scotch crosshead to balance out the reciprocating forces. This makes it possible to operate the press at exceptional speeds and to perform piercing and blanking operations at very high production rates.

Another type of press marketed under the name U. S. Multi-Slide Press features several independent slides or rams actuated by cams whose phases can be adjusted to produce any desired cycle in sequence. The first slide of this press will mount a progressive die of orthodox design so that the stock can feed through the progressive die into an area approached by additional slides or rams from three or more sides, thus making it possible to perform many complicated piercing, bending, and forming operations which otherwise must be accomplished by relatively expensive cam or toggle actuated slides built into the progressive die. This machine is equipped also with an infinitely variable-speed transmission, making it possible to operate the press at optimum speed. Variable-speed transmissions can be used to advantage on other types of stamping presses, particularly for forming operations wherein the velocity of metal flow exerts considerable influence on the forming characteristics.

The Henry and Wright dieing machine is another design of automatic press which has found broad acceptance in the stamping field. It is a single-crank four-post or pillar type of press in which the crank and crankshaft are mounted within the housing beneath the bed. The ram or upper platen is reciprocated by the four posts extending through long bearings in the bed to the crosshead within the housing. This machine can be obtained with automatic roll feeds at both ends as well as with a scrap cutter. The feeding rolls are driven through a unique mechanism featuring a Vernier distribution of pawls acting on ratchet wheels. This makes possible the adjustment of the amount of feed in small differentials over a wide range. Thus it is possible to operate a wide variety of progressive dies at relatively high speed.

SIZE OF A STAMPING PRESS involves several more or less independent specifications. The first of these, the platen or bed area, refers to the amount of clear space available for mounting a die. It is designated by the available distance front to back and left to right in inches. The bed of the press usually has an opening either to permit stamped parts to fall through or to contain air cushions, rubber bumpers, and similar blank-holding equipment for drawing operations. The next dimension of importance is the vertical opening available for the die. This is the distance between the ram and the bed or bolster plate with the ram in its lower position. Since the ram is adjustable over a certain distance, the vertical die opening must be specified with maximum and minimum values. The length of stroke is fixed on all mechanical presses but is subject to adjustment or presetting on hydraulic presses.

Tonnage capacity of a mechanical press of a crank or eccentric type is variable, depending on that part of the stroke at which the maximum force is required. A relatively small short-stroke single-crank press suitable for blanking may have the same tonnage capacity as a much larger toggle press used for drawing operations where the maximum force requirement may come at midstroke. When a single tonnage capacity is specified, as is usually the case with small crank presses, it is applicable only near the bottom of the stroke and is determined for the most part by the diameters of the crankpin and main bearings. On larger presses intended for drawing operations the tonnage capacity should be specified both at midstroke and at the bottom. Tonnage ratings vary considerably with details of design and the conservativeness of the builder.

The energy capacity available for doing the work required in the stamping operation comes from both the drive motor and the flywheel. The amount of energy which is to be supplied by the drive motor during a short working stroke is negligible, and the flywheel must be relied upon for practically all the energy needed at the instant of doing work. However, when some of the larger presses are used for performing drawing operations, the working stroke may be as long as half the total stroke and the drive motor can supply significant amounts of the required energy. These presses are rarely operated continuously, and therefore there is usually adequate idle time during which the motor can store up sufficient energy in the flywheel.

Flywheel slowdown is arbitrarily figured up to 10% for continuous running equipment; up to 20% for intermittent operating conditions; and occasionally up to 40%, which approaches stalling. The working energy W_e, inch-tons, delivered by the average design of flywheel at 10% slow-down may be taken as

$$W_e = \frac{N^2 \times D_f^2 \times W_f}{5{,}250{,}000{,}000} \tag{1}$$

where N = revolutions per minute; D_f = diameter of flywheel, inches; and W_f = weight of flywheel, pounds. For 20% slowdown, multiply W_e by 1.9.

Motor sizes specified for punch presses usually are blanket recommendations to cover the wide range of work which may be put in the all-purpose press. They frequently are high for blanking, forging, or coining operations, and low for deep-drawing operations. In checking, the following approximations may be used:

$$\text{Hp} = 0.005 \times W_e \times n \tag{2}$$

where Hp = horsepower of motor; W_e = working energy, inch-tons; n = number of strokes per minute. Equation 2 holds good in cases where the flywheel has ample energy to meet the total requirements. Otherwise a check should be made with eq. 3 and the higher value used in selecting the motor.

$$\text{Hp} = \frac{1.82 \times n \times (W_{e1} - W_{e2})}{\theta} \tag{3}$$

in which $(W_{e1} - W_{e2})$ is the difference between the job requirements and the available flywheel energy. θ is the working portion of the cycle in degrees.

In eq. 2 the motor may use the entire cycle to build up flywheel energy. In eq. 3 it is selected to carry a portion of the working load. The motor lags some at the beginning of the demand, but then builds up to something over its rating to compensate. An allowance must always be made for friction losses and starting inertia losses, though these are small compared with average working loads.

Punch press motors must be capable of taking a slowdown up to about 10% on continuous running jobs, and up to about 20% (and higher on some jobs) for intermittently operating presses. Squirrel-cage motors are suitable for most work, but high-slip motors often are required on deep draws. Instantaneous peak loads may amount to 100% overload.

FORCE REQUIRED for performing stamping operations can usually be estimated very simply and reliably. The force required to perform all cutting operations can be obtained simply by adding the lengths of all cutting edges in operation at any instant and multiplying the result by the thickness and shearing strength of the stock. The shearing strengths of a large variety of materials are given in Table 1.

All forming operations can be divided into two classes for the purpose of estimating required force. The first group or class of operations is characterized by the fact that application of the punch to the sheet metal sets up tensile stresses directly. Failure or tearing of the metal in tension would reduce or eliminate the force on the punch; therefore a conservatively high estimate of required force will be obtained by multiplying the cross-sectional area of the metal stressed in tension by the ultimate strength of the material in tension. This procedure will provide adequate protection for the press for all types of forming operations, where it is not possible for the punch to bottom against the die. This procedure may give an unnecessarily high value of force requirement for shallow and stretch drawing operations. In such cases the drawn part seldom has vertical walls, a fact which may be taken into consideration by using the cosine of the minimum angle from the vertical as a multiplier. For example, in extremely shallow draws, where the sides of the part are never inclined more than 30 degrees from the horizontal, the vertical component of force which must be furnished by the punch is only half the total force required to rupture the metal. Some authorities recommend using the elastic limit of the metal as well as the angular deviation from the vertical in obtaining a lower estimate of the required drawing force.

In some bending operations and in swaging, embossing, and coining, the punch is permitted to bottom against the die. In these cases it is necessary to multiply the total area which can come into contact by the compressive strength of the material to obtain a reliable estimate of the required force. Even then, it is advisable to add a substantial safety factor as a protection against careless setting-up of the die in the press.

Where pressure pads or draw rings are used for drawing operations this force must also be taken into consideration in selecting the press rating. When stretch drawing is performed in single-action presses, the air cushions limit the load on the ram to that required to hold the blank, the cushions usually are attached to a 100-psi supply. In toggle presses it is necessary to assume that the force required for blank holding will be as much as two times the force required by the punch.

The energy required for cutting operations is estimated by assuming that the cutting force remains constant during the working stroke, which is equal to the per cent penetration required for cutting. The latter value, that is the per cent penetration, can be obtained from Table 1. The energy required by all forming operations, except those of the squeeze group, is estimated by taking 80% of the value obtained by assuming that the force remains constant throughout the working stroke. Energy required for the squeeze operations is relatively small despite the fact that the forces may be very high. This is because the known working strokes are invariably relatively short. In any case, the required energy is assumed to be equal to the product of the compressive force and the length of the working stroke.

9. UNIQUE PROCESS VARIATIONS

There are some unique variations of the stamping process which involve radical differences in design of the dies and equipment as compared with orthodox procedures. Typical of these process variations are impact stamping, the Whistler hydrodynamic process, and the rubber die process. These processes have limited but unique applications as well as unique designs and procedures.

IMPACT STAMPING is the plastic forming of metallic shapes by impact or hammer-like blows. The principal difference between impact stamping on the one hand and conventional and stretch drawing on the other is that the former squeezes or hammers the material between the punch and the die over the entire area, thus stressing more of the material beyond the elastic limit, as is done in striking the corner of a bend. The relatively high velocity of impact stamping is necessary to provide the very high localized forces required to give a set to the metal over its entire area.

For many years silversmiths, cornice makers, and other sheet metal workers have employed rope-lift gravity-drop hammers in their work. Airplane manufacturers adapted impact stamping as metal displaced wood and cloth in airplane construction. World War II accelerated the development of impact stamping and generated the demand for more productive equipment. Impact stamps or hammers, utilizing compressed air for lifting and for accelerating the hammer blow, became available. These not only can form by impact but also have limited pressing capacity. Current application is in bus and truck body building and other shaping where the quantities being produced do not justify steel dies and mechanical presses. They also may be used because of the impact feature which can be used to minimize spring back common to those metals possessing a high ratio of yield point to ultimate strength.

Nonferrous dies are generally used for this process since they can be cast to almost final shape in a very short period of time, thus greatly reducing the die cost. The construction of steel dies to contact the sheet metal over its entire area on both sides would cost even more than the corresponding dies for stretch drawing. The procedure for making the nonferrous dies involves making plaster patterns either from mock-ups or templates. These patterns are used to prepare sand molds for the casting of Kirksite dies and lead punches. After removal from the molds the Kirksite dies are ground and polished. The lead punches being soft require no grinding since they can be made to flow to the contour of the die after mounting in the press.

Air-actuated hammers for performing impact stamping make it possible for the press or hammer operator to control the magnitude of the hammer blow over a very wide range. Some parts can be formed from some materials in a single blow whereas others may require several strokes in a series of either diminishing or increasing blows. It is impossible to exercise this type of control in the orthodox stamping press.

THE WHISTLER HYDRODYNAMIC PROCESS.* The hydrodynamic process is a patented development available for use under license agreement. It is a special variation of a hydraulic die that is particularly well adapted to stamping and stretch drawing operations. The process uses a die consisting of two halves mounted respectively on the upper and lower platens of a hydraulic press. The upper die contains a cavity having the desired shape of the formed part. In operation a previously cut blank is placed on a pressure pad located in the lower half of the die; then the lower platen of the hydraulic press is raised until the sheet metal blank is gripped firmly between the pressure pad and the flange area surrounding the cavity in the upper die. Then water is pumped through the center of the pressure pad, causing the sheet metal to be stretched by a mode of least resistance until it conforms to the shape of the upper die cavity. Many parts which would require several steps for forming in orthodox dies can be formed in one step by this process. A favorable stress distribution makes it possible to form some of the heat-treated alloys of aluminum as well as the highly alloyed, high-strength stainless materials.

---

* Covered by United States Patents 2,066,085; 2,339,775; 2,156,889. And by Canadian Patent 383,472.

THE RUBBER DIE PROCESS. Blanking, piercing, bending, and shallow forming operations can be performed with rubber dies. The rubber, usually in the form of one or more relatively thick blankets, is used to apply a relatively uniform pressure over the entire area of the part or the sheet metal from which the part is being made. Thus with proper application of the pressure the sheet metal can be either cut or formed.

For the cutting operations a hardened tool steel template or punch is mounted on a suitable support at some predetermined distance above the bed of the press; one or more rubber blankets are fastened to the ram of the press and the sheet metal is placed over the tool steel template. The ram is lowered, applying pressure through the rubber to the sheet metal until sufficient stress concentration is set up at the edges of the template to shear the metal. It is necessary that there be enough excess metal beyond the perimeter of the template to permit cutting rather than folding of the metal. The resulting sheared edge is relatively ragged compared to that obtained with orthodox blanking and piercing dies. The final product, however, is good enough even for some load carrying structural parts of air frames. The dies can be made up very quickly so that where small quantities are required it is possible to design and construct the dies and complete the total production run in less time than would be required to build conventional steel dies. Rubber cutting dies can be operated in hydraulic presses, mechanical presses, and even in drop hammers.

A very satisfactory job of forming can also be done with rubber dies. As in rubber cutting dies, the only rubber involved is in the rubber blankets which are used to apply force to the sheet metal. In rubber die forming the sheet metal can be forced either into a die or around a punch, depending on the nature of the part. The solid punch or die is cast from either low-melting metals or from ceramic aggregates. In one variation of this process the rubber blankets are mounted on the lower platen or bed of the press and the sheet metal is placed on top of them: the formed punch is then brought down in contact with the sheet metal, building up sufficient force to form the metal around the punch. In another arrangement the die cavity is mounted on the bed of the press and the rubber blankets are mounted on the movable ram.

The amount of scrap which must be trimmed from parts formed by rubber dies may be considerably greater than that which must be trimmed from the corresponding parts drawn by orthodox procedures. However, it will be recalled that this method is intended primarily for small and medium quantities. Forming with rubber dies can be performed in hydraulic presses and mechanical presses as well as in drop hammers.

SHOT PEENING

By J. O. Almen

The purpose of shot peening is to permit more efficient use of structural metals. Just as earlier generations of designers were enabled to reduce the weight and cost of their structures by the substitution of steel for wrought iron, by the introduction of heat treatment, and by the development of modern alloy steels, so prestressing by several processes, including shot peening, increases the net work that may be obtained per unit weight of machine parts.

10. APPLICATION OF SHOT PEENING

Shot peening is coming into extensive use as the most versatile of the several prestressing processes for strengthening metal machine parts against cohesive failure. Cohesive failures that are characterized by brittle fracture are caused only by tensile stresses and result from (1) impact loads on brittle metals in which the tensile stress acting at the surface is greatly magnified by various forms of stress raisers, (2) stress corrosion in which cracks (usually intercrystalline) propagate through metal that is stressed in tension, and (3) fatigue failures in which, because of the magnification of surface tensile stresses, fractures occur from repeated loads that stress the metals less than their nominal yield stress.

Shot peening is effective against these forms of cohesive failure because it induces residual compressive stress in the surface of the metal being peened. The surface tensile stresses from externally applied loads will be reduced by the amount of the residual compressive stress. The quality of the peening is determined by (1) the magnitude of the induced residual stress, which is a function of the yield stress of the peened metal and the state of strain in the metal at the time of peening, (2) the depth of the induced residual stress, which is a function of the hardness and ductility of the peened metal, the state of strain in the metal at the time of peening, and the characteristics of the shot and the shot stream, and (3) the degree of coverage, by which is meant the number of shot impacts per unit of area.

PROCESS. In the process of shot peening, relatively hard particles—usually spherical chilled cast iron or steel shot—are projected against the metal being peened with sufficient velocity to indent the surface. The indentations at each point of impact result from local plastic yielding of the peened metal. The deformed areas tend to expand elastically, but they are restrained by adjacent, deeper metal that was not plastically deformed by the shot impact. Since the plastically deformed surface layer seeks to occupy more space, it is compressively strained; that is, it is residually stressed in compression.

STRESS-CORROSION CRACKING. Since stress-corrosion cracking occurs only in metal that is stressed in tension, it is necessary to protect the surface by only a thin layer of compressively stressed metal to prevent corrosive attack, even though the underlying material is still highly stressed in tension. Thus welded or cold-formed vessels that are residually stressed in tension from the forming operation, or from the localized heat of welding, and/or from the working loads, may be protected against stress corrosion or season cracking by the corrosion-impervious layer produced by shot peening. Surface corrosion will still occur, and may actually be increased by the increased roughness, but the intercrystalline corrosion characteristic of stress-corrosion cracking will be stopped so long as the surface stress remains compressive. Shot peening will become ineffective against stress-corrosion cracking if the residual compressive stress is lost, as, for example, by applying external tensile loads that exceed the yield strength of the material. When tensile plastic extension has occurred throughout the section, the residual stress induced by peening will have been largely dissipated. Some materials may lose much of the residual stress by slow plastic yielding, usually known as "creep," without the aid of external loads. In such materials, the protection afforded by shot peening will become less effective with time.

IMPACT STRENGTH. The resistance to impact fracture of many brittle materials, such as hard steel, may be increased by shot peening to produce residual compressive stress in a relatively thin surface layer. The hardest steel is still sufficiently plastic to develop residual stress, although the indentations from shot impact may be too shallow to be detected without sensitive instrumentation.

The susceptibility to impact fracture is increased by surface imperfections and discontinuities (often submicroscopic), such as micro-stresses, scratches, minute notches, corroded areas, and similar stress raisers. These stress raisers cannot be eliminated by polishing, but they are rendered ineffective when the surface metal is compressively stressed to a depth equal to the depth of the discontinuities.

The impact strength is increased by an amount somewhat less than the residual compressive stress acting on the "notched" areas. If the effective depth of the notches is greater than the depth of the induced stress, the peening operation will be ineffective. Shot peening will also be ineffective for increasing the resistance to impact failure in metals that are sufficiently plastic to yield under the applied loads. When appreciable plastic yielding occurs, the residual stress induced by the peening operation will be dissipated.

FATIGUE STRENGTH. Fatigue failures, like impact failures, result from tensile stress only. Under conditions of repeated load applications, cohesive failures will occur from stresses considerably less than the nominal yield strength of the material. Since there is no apparent yielding, the fracture will be brittle in character, even though the material is quite ductile as measured by the conventional static tensile and bending tests.

Under ordinary conditions of specimen preparation, fatigue fractures will originate very near the surface, because the surface tensile stress is always augmented by micro-stresses and various kinds of stress raisers, or perhaps because a surface is, itself, a discontinuity. The stress increment that is added by surface stress raisers increases as the ductility of the material decreases until, in hard steel, the effective tensile stress may be several times as great as the nominal stress. As the hardness of steel increases, the effective "notch" stress increases at a greater rate than the potential strength of the steel, and there is, therefore, a well-recognized limit of hardness for best fatigue durability. Thus the upper limit of hardness of ordinary springs lies in the range of Rockwell C 40-45 because of surface vulnerability.

However, this hardness limitation does not apply when the hardness is obtained by carburizing or by nitriding, as, for example, in carburized gear teeth, carburized wrist pins, and nitrided crankshafts. The fatigue strength of machine parts that are surface hardened by these processes generally increases as the hardness increases. This deviation from the rule of brittleness is due to the residual compressive stress that is developed in the surface by the volume increase that occurs in the hardened case. It follows that the surface vulnerability (notch sensitivity) of the hardened surface of the steel cannot assert itself until the initial compressive stress is overcome by tensile stresses from external loads. Since, in most nitrided specimens and in many carburized specimens, the magnitude of the residual compressive stress is of the order of 100,000 to 150,000 psi, the tensile stresses from externally applied loads are often not sufficient to overcome the residual compressive stresses in the hardened case. The surfaces are, therefore, never stressed in tension, and the fatigue failures will originate in the core.

SHOT-PEENING STRESS. The vulnerability to fatigue failure of machine parts and of laboratory specimens is reduced by shot peening because of the layer of uniform residual compressive stress that is induced when the peening process is properly performed. It must be recognized, however, that there are important differences between the protection against fatigue failure that may be gained by the surface-hardening processes previously described and by shot peening. Prestressing by shot peening alone is not so effective as prestressing by several other processes, but it is the most versatile, because it may be applied at relatively low cost to machine parts of all shapes and to metals of all kinds. The magnitude of the residual compressive stress obtainable by shot peening is equal to approximately one half the nominal yield stress of the metal when the peening coverage is adequate and when the peening is performed on the specimen while in an unstrained state. This compressive stress of 50% yield strength is negative to the dangerous tensile stress. It is available to offset surface fatigue vulnerability when, for example, the peening is applied to the tension-stressed side of a beam that is subjected to repeated bending loads in one direction. However, much or all of the protective residual surface stress may be lost from a shot-peened beam that is subjected to repeated reversed-bending loads.

REVERSED-BENDING LOADS. In reversed loading, one side of the beam will be compressively stressed at each load application. The compressive stress on that side will, then, be the residual stress that was induced by shot peening, plus the compressive stress from the external bending load. If this total exceeds the compressive yield strength of the material, the residual compressive stress will be reduced, and a corresponding part of the protection against surface vulnerability will be lost. The actual yield stress under repeated loading is considerably less than the nominal yield stress as measured by static loading, and it is therefore possible to lose all the residual stress induced by shot peening. If all or most of the residual compressive stress is lost, the fatigue strength of the part may actually be less than before peening, because of the increased notch effects in the roughened surface. Such loss of residual compressive stress under repeated reversed-bending loads does not readily occur in carburized and in nitrided parts because of the greatly increased yield strength of the hardened surfaces.

ONE-WAY BENDING LOADS. The residual compressive stress from shot peening is not lost from the tension side of parts subjected to bending loads that act in one direction only. In such parts, the peening need be applied only to the tension-stressed side, and since this side is not compressively stressed by external loads, the total compressive stress remains that which is induced by peening.

Any plastic yielding that may occur on the tension side will increase the residual compressive stress and will therefore tend to increase the fatigue strength of the part. In fact, such yielding actually does occur in nonpeened, as well as in peened specimens, which is one reason—perhaps the principal reason—for the greater fatigue strength of specimens subjected to one-direction loading. The effect usually referred to as "understressing" is also explained by such yielding.

Plastic yielding also occurs on the side of fatigue specimens that are loaded in compression. Such compressive yielding results in residual tensile stresses, which occasionally become great enough to cause fatigue failures to originate on the side nominally stressed in compression. The maximum tensile stress occurs, of course, when the external load is removed. From such occurrences arises the erroneous belief that fatigue failures can be caused by compressive stress.

Because of the greater protection against surface vulnerability that is given to fatigue specimens subjected to one-way bending loads, it is often desirable to increase the compressive stress induced by shot peening. This may be accomplished by performing the peening on the tension side while the part is statically loaded, in the direction of the normal service load, to approximately one-half the yield stress of the material. The peening will then superimpose upon the static tensile stress, compressive stress equal to about 50% yield stress, which will be increased to approximately 100% yield stress when the static load is removed. The static load to be applied during peening should not exceed 50% yield stress because, upon relaxing the external load, the compressive stress will exceed the yield strength, and plastic deformation will occur. This plastic deformation will be in the opposite sense to the plastic deformation that occurred during shot peening, and the surface layer might be damaged by being excessively cold worked.

FATIGUE TESTS MAY BE MISLEADING. From the foregoing, it will be seen that it is not possible to evaluate the effect of shot peening or to measure the fatigue strength of parts that, in normal use, are to be loaded in one-direction bending, by subjecting them to reversed-bending fatigue tests. This is also true of specimens in which favorable residual stresses have been developed by understressing and by such processes as surface rolling, overloading to cause yielding, and quenching from tempering temperature.

MEMBERS LOADED IN TORSION. It is usually convenient to consider members that are loaded in torsion to be stressed in shear. However, to understand the effects of prestressing, it is necessary to apply a stress pattern that may be expressed in terms having positive and negative values. Therefore, instead of shear, the tensile and compressive stress components of the shear stress are used. These stresses act at angles of 45 degrees to the shear plane and at right angles to one another; that is, when the tensile stress acts in the direction of a right-hand helix, the compressive stress will act in the direction of a left-hand helix.

In repeated reversed-torsional loading, the tensile and compressive stresses are reversed at each load application, and therefore the residual compressive stress induced by shot peening may be lost, wholly or in part, in the same manner as in specimens subjected to reversed-bending loads.

For torsional loads that are applied in one direction only, the residual compressive stress acting in the direction of the tensile stress component remains fully effective. Much or all of the residual compressive stress acting in the direction of the compressive stress component may be lost by plastic yielding, but this loss does no harm unless the yielding is so extensive as to induce dangerous residual tensile stress when the external load is at its minimum.

For greater protection against fatigue in one-way torsional loading, the magnitude of the residual compressive stress induced by shot peening may be increased by performing the peening while the specimen is statically loaded, in the normal direction of twist, to approximately half the yield stress of the material. The surface stress prior to peening will then be one-half the tension yield stress in the direction of the tensile stress component and one-half the compressive yield stress in the direction of the compressive stress component. After peening, while still statically loaded, the surface stress in both directions will be compressive and equal to one-half the yield stress of the metal. The peening will not have altered the surface stress in the direction of the compressive component, but in the direction of the tension component the surface stress will have been changed from one-half the yield stress in tension to one-half the yield stress in compression, a plastic flow representing 100% of the yield stress of the metal.

Upon release of the external load, the bar will untwist to nearly its original angle of zero stress. In so doing, however, the strain in the direction of the tensile component will increase the compressive stress and the strain in the direction of the compressive component will reduce the compressive stress. The residual compressive stress will then be, roughly, 100% of the compressive yield stress in the direction of the tensile component and zero stress in the direction of the compressive component. Since, under ordinary test load range from zero to maximum, slow yielding will occur under repeated loading, the residual compressive stress in the direction of the tensile component may decrease slightly to equal the dynamic compressive yield stress. In the direction of the compressive component, tensile residual stress will be induced by slow yielding. Extensive plastic yielding by creep, added to the plastic deformation that occurred during peening, may damage the material sufficiently to cause fatigue failure from the induced tensile residual stress, which acts in the direction of the nominal compressive stress. Being residual, the maximum tensile stress, which may cause fatigue fracture, occurs when the external load is removed. Since the fatigue fracture will originate on a line at right angles to the tensile stress causing the failure, it is possible, by observing the direction of the initial fracture, to determine whether the failure was caused by the tensile component of the external load or by induced residual tensile stress acting in the direction of the compressive stress component. Fracture from induced tensile stress cannot occur from a test in which the load is varied from the same maximum, but to a lesser minimum: for example, in a test in which the load range is plus 25% to plus 100%. This again demonstrates that the effect of shot peening cannot be evaluated by an arbitrary test procedure based on nominal stress or nominal stress range.

AXIAL-LOADED SPECIMENS. A few machine parts, and occasional fatigue specimens, are loaded in tension or in combinations of tension and compression. Shot peening will increase the fatigue strength of specimens repeatedly loaded in tension by reducing the subsequent tensile stress in the vulnerable surface layer. However, since the residual compressive stress in the surface layer must be balanced by tensile stress in the core to maintain force equilibrium, the total tensile stress in the core will be the tensile stress from the external load, plus the residual tensile stress. If the area of the specimen is small in relation to the depth of the peened layer, the residual tensile stress may become so great as to require only a small external tensile load to cause subsurface fatigue failure. Slight peening may be very beneficial from the standpoint of fatigue, and heavy peening may be very harmful.

Under push-pull fatigue loading, the residual compressive stress from shot peening may be lost, in whole or in part, depending on the magnitude of the external compressive load. When the residual compressive stress is lost, the specimen will have been damaged by shot peening because of the increased stress raisers created by the peening.

CARBURIZED AND SHOT-PEENED METALS. The residual stress that results from carburizing can be made much more effective by shot peening as a final operation. The residual stress from carburizing extends to the depth of the hardened case, and the compressive stress is of the order of 100,000 psi. However, the maximum stress occurs at some depth, with considerable loss of stress near the surface. Shot peening effectively increases the maximum compressive stress, and, since the compressive yield stress in the hardened case is great, there will be little loss of residual compressive stress during fatigue testing or in normal service. The fatigue fracture will often originate in the core in carburized and shot-peened specimens, for the reason that the surface stress does not become tensile For a given specimen, a close approach to the best possible treatment will have been attained when fatigue fractures in successive specimens originate with equal frequency at the surface and in the core. This must not be taken as "best," however, because the relative areas of core and case may be such as to stress the core in tension unduly.

An effect similar to carburizing may be obtained by other case-hardening processes. In steel sections of adequate diameter, low-hardenability steel, such as severely quenched SAE 1040-1050, will harden only in a relatively thin case. This hardened case will be residually stressed in compression because of the volume increase upon hardening, just as occurs in a carburized case. The fatigue strength of such specimens in bending and in torsion may be further increased by shot peening.

TREATMENT FOR BEST FATIGUE STRENGTH. For repeated reversed loading in bending and in torsion, the best fatigue strength from prestressing of steel is obtained by case hardening followed by shot peening. The deep, and relatively great, residual compressive stress reduces the tensile stress from external loads, and the high yield strength of the case prevents serious loss of the protective stress. Shot peening is not required for nitrided parts, because the residual stress is sufficiently great as heat treated.

For one-way bending or one-way torsion, the best fatigue strength may be obtained from parts that are deep hardened. The material may be in the hardness range Rockwell C 50-55, it should be overloaded to produce plastic yielding in the same direction as the normal load, and, finally, it should be shot peened while statically loaded to approximately half the yield strain.

Because of the suggested hardness of the specimen, the operation of prestressing by overloading is hazardous, particularly since the plastic deformation should be extensive enough to extend to approximately 15 to 20% of the specimen thickness. Unless suitable precautions are observed, this extensive cold setting may damage the material and may even cause immediate fracture. The overloading should therefore be applied at an elevated temperature to reduce the yield stress temporarily and to increase the ductility of the steel. Shot peening at one-half yield strain prior to presetting will also aid in preventing fracture or other damage during the presetting operation. Finally, the shot-peening operation should be applied while the part is statically loaded in the direction of the normal load to approximately half the yield strain.

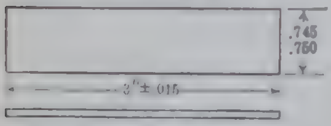

FIG. 1. Almen shot-peening test strip. Specifications are: Hardness, Rockwell C 44-50, flatness, ±0.0015 in. on Almen gage; *A* strip thickness, 0.051 ± 0.001 in.; *C* strip thickness, 0.094 ± 0.001 in. Ends only may be shear finish, burrs must be removed and corners broken.

11. SHOT-PEENING INSTRUMENTATION

To specify that a machine part is to be shot peened without stating how much, in measurable quantities, is equivalent to specifying "heat treat" without mentioning temperature or time. To meet this need, instrumentation is available that is sufficient for the purpose in accuracy, cost, and simplicity.

The principal instrument that is used for measuring, and thereby controlling, shot peening consists of a standard steel strip (Fig. 1) that is shot peened on one side while attached by screws to a heavy hardened steel base (Fig. 2). When the test strip is removed from the heavy base after peening, the residual compressive stress that was induced causes convex curvature of the strip on the peened side. The curvature is measured on the unpeened side in terms of arc height over a standard chord by a special indicator (Fig. 3).

The amount of curvature, that is, the measured arc height of the strip, is called *peening intensity*. The peening intensity is the overall effect of the magnitude of the induced stress, the depth of the stressed layer, and the uniformity of the stress, in magnitude and in depth, over the surface of the strip—hereafter called the *coverage*. Since the peening intensity measurement is made on a steel strip of standard dimensions and standard physical properties, the magnitude and depth of the induced stress are those of the test strip and not of the metal being peened.

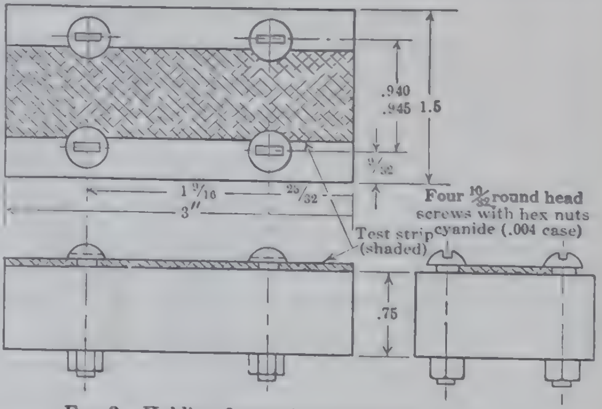

FIG. 2. Holding fixture for shot-peening test strip.

Two thicknesses of test strips have been standardized to meet the needs of sensitivity for light and for severe peening. The dimensions of the two strips, designated as *A* strips and *C* strips, are given in Fig. 1. A chart correlating peening intensity readings from *A* strips and *C* strips is shown in Fig. 4.

In production use, the hardened holding fixture (Fig. 2), with attached test strip, is passed through the peening machine in the same manner as the parts being peened. The surface of the holding fixture, to which the test strip is attached, is located in such a way as to represent a critical area of the work, in order that the peening received by the test strip will be substantially the same as is received by the work. Usually, the holding fixture is welded or bolted to a dummy machine part that has been prepared for the purpose. Complex machine parts having many angles and planes may require a number of holding blocks, each representing a different plane or critical area of the work. Peening intensity measurements are made several times each working day. New test strips are used for each location every time the measurements are made.

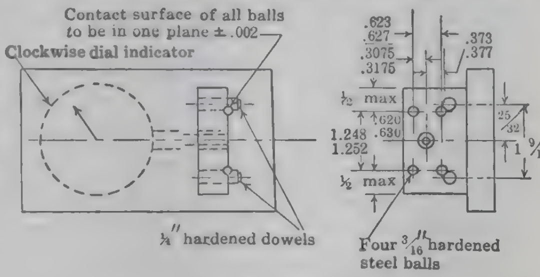

FIG. 3. Almen gage.

Peening intensity is a measure of the quality of the shot stream which may be likened to the measurement of temperature in a heat-treating operation. The temperature of the metal being heat treated is usually arrived at indirectly by measuring the temperature of the furnace in the vicinity of the work and exposing the work to that temperature for a sufficient time to saturate the metal. Unless both temperature and time are correctly specified, and unless the specifications are followed, the heat-treating operation cannot be successful.

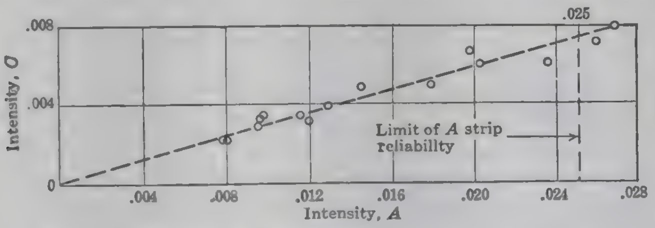

FIG. 4. Correlation of gage readings for Almen *A* and *C* strips.

12. PEENING SPECIFICATIONS

A shot-peening specification consists of the indicator reading for the test strip, which is the arc height in inches, followed by the letter designating the strip size.

Shot-peening specifications must take into account the dimensions and physical properties of the peening shot, the characteristics of the shot stream, and the physical properties and manner of loading of the machine part being peened. The factors affecting peening intensity are shot size, shot velocity, coverage (quantity of shot per unit area), shot cleanliness, direction of shot relative to work, and shot quality (hardness, mass, shape, etc.).

SHOT SIZE. A system of peening shot sizes has been adopted by the Society of Automotive Engineers and accepted by shot manufacturers. This standard designates shot size by a number which is the nominal shot diameter in mills, preceded by the letter "P" to distinguish peening shot from shot intended for other purposes. Table 1 is a reproduction of the shot-size specifications included in the SAE Recommended Practice.

The selection of shot size depends on (1) the radii of fillets and of surface irregularities such as indentations and cutter marks, (2) the section thickness of the work, (3) the appearance desired, (4) the abrasion desired, and (5) the manner of loading the peened part.

Radii of Fillets. The radius of the shot should be approximately half, or less than half, the radius of the smallest fillet or surface irregularity in the critical area. This rule does not apply to shallow cutter marks or scratches, the depth of which is small with respect to the depth of the compressively stressed layer. If the radii of the shot are large with respect to the radii of deep cutter marks or of fillets, the compressive stress induced in these regions will be too small to afford effective protection.

Section Thickness. When the thickness of the work being peened is small compared to the size of the shot, there is danger that the induced compressive stress will extend too

Table 1. Peening Shot Numbers and Screening Tolerances

Maximum "fines" allowed through smallest screen, 3%.
The shot number is roughly the size of the shot pellets in thousandths of an inch.
Percentages given are on the basis of weight.

deeply into the work instead of affecting a relatively thin layer, as is desired. The diameter of the shot should be less than the thickness of the work, since the depth of the compressively stressed layer increases as the shot diameter increases.

Appearance. The section thickness of the work also influences the shot size from the standpoint of appearance of the peened surface. Coarse peening is less offensive to the eye on thick sections than on thin sections.

Abrasion Desired. The amount of material that is abraded from the surface of the work, for any peening intensity, is greater when small shot is used than when large shot is used.

Loading of Part. For any shot velocity, the thickness of the compressively stressed layer is roughly proportional to the shot diameter. The desired thickness of the compressively stressed layer will depend on the manner in which the peened part is loaded in service, as well as on the section thickness. For members loaded in tension and for surfaces where peening has been superimposed on a deep prestress obtained by other means such as carburizing or overstressing, the compressively stressed layer should be thin. For members loaded in bending or in torsion, which are not otherwise prestressed, the compressively stressed layer should be relatively thick.

SHOT VELOCITY. The shot velocity that will be required for any specified peening intensity will vary with (1) the size of the shot, (2) the hardness of the shot, (3) the mass of the shot, and (4) the direction of the shot relative to the work.

Size of Shot. The size of the shot affects the shot velocity to be used for any specified peening intensity, because the depth of the compressively stressed layer is proportional to the shot size.

Hardness of Shot. If the shot is so soft as to deform on striking the work, some of the shot energy will be lost. The shot will also present greater areas of contact, and therefore the unit pressure and the peening intensity will be reduced unless velocity is increased.

Mass of Shot. The energy of the shot will vary with its mass and with its velocity. If the mass of shot is changed, it is necessary to change the velocity to maintain constant peening intensity.

Direction of Shot. The energy of the shot that is absorbed by the work will vary approximately as the sine of the angle between the plane of the work and the line of motion of the shot. To maintain constant peening intensity of the work, it is therefore necessary to change the velocity of the shot as the angle of impact is changed.

COVERAGE. By *coverage* is meant uniform distribution of peening stress over the surface of the work. Uniform stress means that the points of impact are so numerous that the stress induced by each impact overlaps the adjacent stressed area to produce essentially uniform stress.

The same instruments that are used to measure peening intensity are used to determine the time of exposure of the work to the shot stream to obtain adequate coverage. Since the total residual stress will continue to increase until the peened surface is uniformly stressed, the curvature of the test strip will continue to increase until saturation is attained.

Figure 5 is a chart of peening intensity plotted against time of exposure. The upper curve shows a condition in which the specified peening intensity reading is attained at *A*, but since the curve continues to rise with increased time of exposure, it is evident that the peening stress at point *A* was not uniform; that is, the coverage was inadequate.

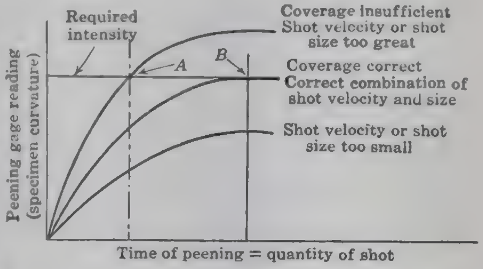

FIG. 5. Peening intensity versus time of exposure.

The second curve shows correct combinations of shot size and velocity so that the required peening intensity is attained at *B* after a time of exposure sufficient to saturate the surface.

The lower curve indicates conditions under which the desired peening intensity cannot be attained because of insufficient depth of the induced stress.

To determine the time of exposure required to obtain adequate coverage, successive test strips are passed through the shot stream, varying only the time of exposure. The arc height reading of each strip is plotted against the time of exposure, as in Fig. 5. Alterations are then made in shot velocity or in shot size until the required peening intensity is obtained as the limit of arc height is approached.

SHOT CLEANLINESS. Good peening requires that only reasonably round shot of uniform size be used in the machine. Since a considerable percentage of normal commercial shot will eventually fracture or wear as a result of repeated impact against the work or against the wall of the cabinet, means have to be provided for discarding split or other fractured shot, undersized shot, and dust.

Undersized shot, split shot, and smaller fragments are objectionable because they (1) reduce peening intensity, (2) increase abrasion, (3) cut, rather than peen, (4) contaminate the surface of the work, and (5) increase the cost of peening.

1. Peening intensity is reduced because the small particles strike the work with less energy than the original-sized particles.
2. Abrasion is increased because the broken, sharp-edged particles wear away the surface much more readily than the round shot.
3. Many of the broken shot cut into the work like a knife, and may therefore reduce the fatigue strength of the work, since such cuts may extend deeply into the compressively stressed layer.
5. To maintain the specified peening intensity, it is necessary to increase the velocity as the shot breaks down. This increased velocity accelerates the breakdown of the remaining whole shot as well as the added new shot, thus requiring more replacement than if only clean, round material of the specified size were used. As the shot size is decreased, not only must the velocity be increased, but often the time of exposure must also be increased.

SHOT QUALITY. Under shot quality may be listed such properties as (1) hardness, (2) impact fatigue strength, (3) shape, (4) soundness, (5) size range, and (6) mass.

Hardness. Residual compressive stress can be induced by shot softer than the material being peened, but, generally, shot should be as hard as, or harder than, the work. If the shot is too soft, it will lose its energy in deformation, and the induced stress in the work will be too small to produce the desired compressive stress unless the velocity is increased.

Impact Fatigue Strength. The rate of fracture of sound shot, used in peening, is measured by the impact fatigue strength. The impact fatigue strength of commercial chilled iron shot is low—hence the importance of good devices for separating fractured material from whole shot.

Table 2

Name of Part	Material	Hardness (R_c or Equivalent)	Thickness of Critical Section, in.	Surface Finish before Peening	Manner of Stressing	Kind of Shot Used	Size of Shot	Peening Intensity
Crankshaft	Steel	10-21	0.75	Polished	Reversed torsion	Chilled iron	P-28	0.014-0.015A
Connecting rod	Steel	37-44	0.16	Polished	Reversed torsion	Chilled iron	P-19	0.015A

* Carburized.

Shape. The shape of the shot is important from the standpoint of uniformity of peening. However, it is not commercially possible to obtain only true spherical shot.

Soundness. A considerable percentage of normal chilled-iron shot is hollow. This usually fractures more readily than sound shot and is quickly eliminated when an adequate separator is used.

Size Range. The range of size of commercial screened shot has been specified by the Society of Automotive Engineers.

Mass. Shot for peening purposes may be made from material other than chilled iron or steel. For example, aluminum may be peened with glass shot, granules of plastic material, or walnut shell granules. These alternate materials avoid electrolytic corrosion, especially in magnesium, and the walnut shell and plastic granules also avoid abrasive contamination. The softer peening materials are not capable of inducing residual stress in steel; hence the standard peening intensity strip cannot be used to measure peening intensity. Aluminum or other soft metal strips, not yet standardized, will serve, however.

It is not possible to generalize with regard to peening intensity specifications because of the wide variety of machine parts made from many kinds of metals variously loaded and heat treated. As in specifying heat treatments, each case presents problems peculiar to itself. It will perhaps be helpful to indicate peening intensity specifications that have been reasonably successful when applied to typical machine parts. Such data are presented in Table 2.

WELDING OF METALS

By C. W. Obert

1. TYPES OF WELDS

Recent developments and advances have given the welding art a dominant place in the metal industries. It has become common practice to shape and prepare metal parts and then join them by welds to produce engineering structures. It is the purpose of this chapter to classify the processes by which welds of various types are applied and to outline their heating conditions as well as the effects that result therefrom; to refer to the important engineering materials that can be welded, the physical properties of the resulting welds, and the design requirements thereby influenced. Reference will also be made to the allied processes of surfacing and hard facing. Metal cutting by flame is discussed in Section 23.

A weld is defined as a localized coalescence of metals wherein coalescence is produced by heating to suitable temperature, with or without the application of pressure and with or without the use of filler metal. The welding heat may be derived from a number of different sources, and the processes of applying the heat are divided into two general groups: (1) methods in which the joint surfaces are heated to the temperature range in which the metal becomes sufficiently plastic and pressure is then applied; and (2) methods in which the joint surfaces are heated above the melting temperature of the base metal and fusion obtained without application of pressure (fusion welding). These two main divisions are further classified according to the source of the welding heat: for example, the plastic or pressure processes are subdivided into forge welding, oxyacetylene-pressure welding, electric-resistance welding, and thermit-pressure welding; the fusion welding processes are subdivided into gas welding, electric-arc welding, and thermit welding.

FORGE WELDING is the oldest form of welding. The parts to be joined are heated locally to the proper temperature range and then subjected to pressure by hammering or rolling, either by hand or by machine. This process is used for a wide variety of applications, from the miscellaneous work of the blacksmith to the joining of steel plates up to approximately 2 in. thick in the fabrication of boiler drums and other pressure vessels. Large tonnages of lap-welded and butt-welded tubes have been produced by passing heated formed skelp through pressure rolls. Forge welding has been largely superseded by more recent welding processes.

OXYACETYLENE-PRESSURE WELDING. There are two methods by which gas welding utilizes pressure to make the welding. In the first, carefully machined and cleaned ends of pieces are butted tightly together under pressure; then heat is applied. This application of pressure welding is characterized by the fact that the bond is formed by diffusion and recrystallization at a temperature lower than the melting point of the materials being joined. Closed-face pressure welding is the only process effecting the bond completely in the solid phase. The second method involves heating with flames impinging directly on the welding faces, which have been spaced a short distance apart. These faces have previously been made substantially square. When the ends of the pieces have been brought to the fusion point, the parts are rapidly joined under pressure to effect the weld. In both processes an upset is created by the shortening of the parts. No filler metal is added in either process.

In oxyacetylene-pressure welding, the strength of the joint can be made equal to that of the annealed base metal. The finished weld is homogeneous, and there is no evidence of the juncture except where steels of different alloy content have been joined. Dissimilar metals react differently to an etching reagent, and the area of the joint can be detected although no fine line of demarcation exists under microscopic inspection.

RESISTANCE WELDING. The various electric-resistance welding processes are in principle similar to forge welding in that the weld is made by application of pressure while the surfaces being joined are heated to plastic temperature or even to the melting point. All resistance-welding processes involve local heating of the parts to be joined by the passage of a heavy current across the joint. Heat is generated locally at the joint by the

---

Revision of material originally prepared by J. C. Dodge and R. E. Hiller.

greater electrical resistance of the circuit at the joint contact surfaces. Either direct or alternating current may be used, but generally it is most convenient to use alternating current, since the desired high amperage at low voltage is readily supplied through suitable transformers. Because of the high current required and the necessary "push-up" forces, the surfaces which may be joined by this method are limited. For a given cross section to be welded, the power requirements vary widely with the time interval of current application to produce the weld. For the usual resistance butt or flash weld, with low-carbon steel, requiring a heating period of several seconds, 30 kva or more are required per square inch of weld surface. As the time interval is decreased the power requirement increases; where welds are made in a fraction of a second, 1500 to 2000 kva per sq in. are not uncommon. The necessary pressure or push-up force applied after the joint surfaces have been heated to plastic temperature is approximately 5000 psi of weld surface.

Resistance-welding processes are particularly applicable to mass production because special equipment is required for each type of welding job.

Electrodes for introducing the welding current into the work are generally faced with a hard copper alloy to avoid excessive replacement, which would be necessary if soft copper alone were used.

Resistance Butt Welding. In resistance butt welding the parts to be joined are pressed into contact, and electric current is passed through the grips (electrodes) and across the junction of the two parts. When the temperature of the contact surfaces has reached the plastic range, pressure is applied, and upsetting of the plastic metal to a greater or less degree accompanies the making of the weld.

Electric-resistance flash welding is a modification of resistance butt welding and is carried out in much the same manner. Contact edges are slightly separated, however, and arcing or flashing occurs from edge to edge of joint. This arcing may burn or flash off a considerable amount of metal at the joint before the ends become sufficiently hot to form the weld by pressure. During the flashing period this loss in metal is compensated by feeding the two edges together to provide a uniform distance between them. Pressure is applied after flashing has heated up the contact surfaces to welding temperature. Flash welding is applicable to the welding of larger joint areas than resistance butt welding. This method also requires less care in the preparation of joint surfaces and smaller current densities for satisfactory welding than resistance butt welding. Often a hydrogen atmosphere is maintained at the weld to prevent oxidation of the joint surfaces.

Both butt and flash resistance welding processes are widely used for joining ends of wires, bars, and tubes. They have been more recently developed for producing tubing from flat strips by a continuous longitudinal butt weld as the formed strip passes through electrical contact rolls. In such tube welding processes, very high currents are utilized, the weld being effected at point of contact in a fraction of a second.

After completion of the weld, it may be heat-treated in the resistance welding machine, the current being used to bring the portion between the grips or electrodes to the desired heat-treating temperature.

Resistance spot welding is applied to the welding of overlapped metal sheets or other comparatively thin sections. The overlapped parts are held between electrodes, which apply pressure while electric current is maintained through them; the current is cut off before the pressure is released. The area welded is approximately the same size as the electrode tip, usually $1/8$ to $1/4$ in. in diameter. Spot welding is particularly applicable to fabrication of metal sheets up to $1/4$ in. thick, but it may also be applied to heavier sections. Automatic equipment makes possible the production of many welds per minute.

Shot welding is spot welding in which an extremely high welding current is applied for a short period of time. This method is particularly valuable for the welding of certain alloy steels such as nickel-chromium steels where time at welding temperature is harmful to the metal. In spite of the large welding currents employed, the total heat required is relatively small because of the small time interval of current application.

Resistance seam welding may be considered as a series of overlapping spot welds, the electrodes generally being in the form of rolls which also transmit pressure as the overlapping sheets pass between them. Automatic equipment for this type of welding generally utilizes a current interrupter which so times the current impulses with relation to the speed of travel of the sheets that a series of overlapping spot welds actually results.

Percussive welding processes are forms of resistance welding in which electrical energy is discharged suddenly at the junction, accompanied by the application of pressure. Closing of the discharge circuit often accompanies the bringing of the two parts into contact with pressure. The energy discharge may be obtained from a condenser, or by the transformation of the energy stored in a magnetic field by the collapse of the field.

THERMIT-PRESSURE WELDING. A modification of the thermit process is the thermit-pressure method of butt welding. This is applicable to joining such parts as rails, tubes, or bars which may be conveniently pressed together by end pressure. The surfaces to be joined are butted together, and the thermit slag and metal poured into the mold around the joint. The alumina slag produced in the thermit reaction is poured into the mold first and covers the surfaces of the parts. The superheated metal does not come into direct contact with the parts but heats them to the plastic temperature range. When the ends are heated, as judged by a suitable time interval, pressure is applied and produces what is essentially a forge weld. The thermit metal and slag may be removed later.

NONPRESSURE FUSION WELDING PROCESSES. These processes do not involve the union of plastic metals but utilize fusion of the metal to effect the desired union. The joining is accomplished by fusion of the surfaces of the parts. The fused metal is generally obtained by deposit of suitable filler metal which fuses with the base metal, although in some applications abutting or overlapping edges are merely fused together to form the joint.

GAS WELDING. In this fusion welding process the welding heat is obtained from a gas flame, oxygen and acetylene being generally the gases used. Fuel gases other than acetylene may be used in combination with oxygen. With the oxygen-acetylene combination a flame temperature of 5000 to 6000 F is obtained. By varying the proportions of oxygen and acetylene, a neutral, reducing, or oxidizing atmosphere may be obtained. For most purposes a neutral or slightly reducing atmosphere is used. The process is applied successfully to the welding of practically all metals. It is of particular advantage in making welds of any shape or position on comparatively thin sections, especially at sharp edges and corners. It is not, however, limited to thin sections, but may be satisfactorily used to produce welds in heavy metal parts. For joining thin parts, a filler metal may or may not be required, but for thicker sections a filler rod of suitable composition must be used. The reducing flame protects the molten metal from oxidation, but in the welding of some materials a flux is necessary to help remove oxides.

The fuel gas and the oxygen are mixed for combustion in a suitable torch which has regulating valves that allow a flame having the desired characteristics to be produced. The oxygen is generally supplied to the torch through hose connections from compressed gas cylinders, in which it is charged at pressures up to 2000 psi, so that pressure-reducing regulators are needed to control the pressure at the torch. The acetylene may be obtained from transportation cylinders or, if large quantities are required, it may be derived from generators that produce acetylene by reaction of calcium carbide and water.

ARC WELDING. In arc welding the welding heat is obtained from an electric arc formed between the base metal and an electrode, or between two electrodes. Welding current may be either alternating or direct. Depending on the character of the electrode, conventional arc welding is designated as either *carbon arc welding* or *metal arc welding*. In both processes the heat is highly localized and the temperature of the molten metal is considerably higher than in gas welding. Arc voltages vary from 15 to 45 volts, and the arc current from 20 to 600 amp, although some processes use current values as high as 2000 amp. The magnitude of the current that can be successfully used depends on the size of the electrodes, thickness of parts being welded, and rate of weld travel.

In arc welding a molten pool forms on the work at the arc location. By manipulation of the electrode the molten pool is made to travel along the joint as desired. Additional metal is introduced by a filler rod with the carbon arc process. In the metal arc process, the molten metal is supplied by melting from the tip of the electrode. Metal arc welding is more readily adaptable to a wider variety of applications than carbon arc welding.

The carbon arc method is always used with direct current, and for most purposes with the electrode negative in order to avoid excessive consumption of electrode and absorption of carbon in the weld metal. The procedure, essentially a puddling one, is not adapted, to welding in the vertical or overhead positions. Its best application is in automatic welding in the flat position, in which it is general practice to shield the arc and molten metal from the atmosphere by introducing a combustible material and fluxing agents into the arc. The method has had wide application for high-speed welding of thin sections in the fabrication of steel barrels, tanks, and light tubular products. It has also been used for welding heavy sections in pipe and pressure vessels.

The metal arc method carries metal across the arc from the electrode to the work in very small globules and deposits them in the molten pool on the work. The electrode is consumed, and the metal is deposited at a rate dependent on the current used. By proper choice of electrodes, either direct or alternating current may be used. The procedure is adaptable for welding of sections $^1/_{16}$ in. thick or more and may be carried out in flat, vertical, or overhead position. Best-quality welding is obtained by protecting metal in the arc from oxygen and nitrogen of the atmosphere by covering the electrodes with suitable fluxing materials and combustible agents. These exclude oxygen and nitrogen from the arc and give a slag covering to the pool of molten metal. A wide variety of electrodes are available for particular applications. The method is the most versatile and most widely used of the various fusion processes.

ARC-WELDING EQUIPMENT. Either alternating or direct current may be used for arc welding, depending on the type of electrodes. Carbon electrodes, bare wire, and covered electrodes with covering principally of combustible materials generally require direct current. Covered electrodes with covering principally of minerals are, in general, satisfactory for direct or alternating current. Alternating current has the advantage of minimizing arc disturbances created by magnetic fields, and is conveniently supplied from power lines through transformers.

Motor-generator Sets. The most satisfactory source of direct current is a motor-generator set. The most common type is a portable unit, supplying one arc. The generator is of the variable-voltage type, which adjusts its output voltage to the arc demands. A less common unit is a larger set, suitable for supplying several arcs. This type usually has a constant-voltage type generator to supply 70 to 100 volts. The voltage for individual arcs is adjusted by resistances in each line.

Alternating current is supplied from single-phase transformers, either with variable-voltage taps or with a variable inductance in each arc circuit to obtain desired current values. To obtain the necessary constant-current characteristics, inductance always is employed, although sometimes it is inherent in the transformer design. The magnitude of the constant current may be adjusted by varying the inductance.

The amount of current required for each size of electrode will vary considerably with the type of coating and the mass of metal being welded. Approximate values are listed in Table 1. These values are for usual manual or automatic welding procedures. Some special methods use currents as high as 1500 to 2000 amp with metal electrodes of $^{1}/_{2}$ in. diameter or larger. One such method uses a bare electrode and keeps the arc completely buried in powdered flux.

Table 1. Approximate Current for Various Electrodes for Welding Steel

Electrode Diameter, in.	Current Required, Amperes		
	Carbon	Bare Wire	Heavy-coated Electrodes
$^{3}/_{32}$	....	50– 80	60–100
$^{1}/_{8}$	....	75–125	80–150
$^{5}/_{32}$	40	100–175	125–200
$^{3}/_{16}$	75	150–225	150–250
$^{1}/_{4}$	100–200	200–300	225–400
$^{5}/_{16}$	200–400	....	275–500
$^{3}/_{8}$	300–500	....	350–700
$^{1}/_{2}$	400–700	....	....

Electrodes. All important metal arc welds now are made with covered electrodes because of the greater strength and ductility of the weld metal as compared to that obtained from bare wire. A large variety of materials is used for covering electrodes, but coverings may be classed as those consisting principally of combustible material, those consisting principally of mineral substances, and those using a combination of combustible and mineral materials. The combustible type gives protection to the arc largely by producing a gaseous envelope about the arc which excludes oxygen and nitrogen. The mineral-coated types give protection by forming a slag coat on the individual globules of metal as they are transferred through the arc and providing a heavy slag layer over the weld metal pool. The action of this slag may be considered similar to that of slag in steel-melting furnaces. The coverings of electrodes also aid in stabilizing the arc and, to a very large degree, determine the welding characteristics of the electrode. Electrode coverings also may be used to some extent for introducing alloying elements into the weld metal.

ATOMIC-HYDROGEN WELDING is actually a combination of both arc welding and gas welding. A stream of hydrogen is made to pass through an electric arc established between two tungsten electrodes. The heat of the arc causes disassociation of the molecular hydrogen to the atomic form. After passing through the arc the atomic hydrogen recombines into the molecular form, liberating the heat obtained originally from the arc. The atomic-hydrogen flame is used in fundamentally the same manner as the oxyacetylene flame. This process is of particular advantage for welding along edges and corners of thin sections. Its uses include welding stainless steels. The hydrogen flame gives excellent protection to the readily oxidizable chromium in these steels. Filler metal of suitable composition may be melted in the atomic-hydrogen flame as required.

INERT GAS-SHIELDED ARC WELDING. This is an electric-arc welding process that employs a blanket of monatomic inert gas to shield the weld area. Highly concentrated heat is produced by an arc drawn between a single, virtually nonconsumable tungsten electrode and the work piece. The inert gas (argon or helium) is fed through a nozzle surrounding the electrode in the head of the torch and flows out to blanket the electrode completely, as well as the arc and weld puddle, for the total exclusion of the oxidizing atmosphere.

The process is used successfully for welding magnesium, aluminum, stainless steel, high-alloy steel, nickel and nickel alloys, brass, silicon bronze, pure silver, and other metals. The outstanding characteristic is that all these metals can be welded without the use of flux. Because no flux is needed, corrosion from entrapment of flux in the weld is eliminated.

The necessary equipment consists of a torch used to hold the electrode and to provide a means of getting the helium or argon around the weld; a tungsten electrode; a supply of inert gas, governed by a regulator and measured by a low-pressure flowmeter; and a source of electric current.

Direct current of either polarity or alternating current may be used; the choice depends somewhat on the alloy and the thickness. Reverse-polarity direct current (electrode positive) has been used for welding magnesium, but many fabricators prefer alternating current because of its greater penetration, speed, and range of thickness capacity. Likewise, alternating current is almost always used for welding aluminum since straight-polarity direct current does not produce a satisfactory weld. For stainless-steel alloy steels and some copper alloys, either alternating current or direct current may be used. Alternating current is generally preferred for light material because of better arc stability. Direct current is favored for heavier material because of the deeper and narrower weld beads.

SUBMERGED-ARC WELDING PROCESS. This is a method of welding electrically beneath a protective layer of granular and molten mineral material. The process is used for welding virtually all steels, as well as other ferrous and nonferrous metals and alloys. The granular material is usually laid down directly ahead of the welding zone. In the welding zone, the granular material fuses and protects the weld from the effects of the atmosphere. Since the atmosphere is excluded from the weld, bare welding wire can be fed directly into the welding zone. There is no flash, glare, or spatter. The molten slag also removes impurities from the weld, and as it cools it solidifies, forming a protective cover over the weld. When cool, the fused material cracks off or can be removed easily. The welds produced are dense and uniform, and are as strong as the parent metal, or stronger.

The use of the process is limited only by the capacity of the equipment. With present equipment, material ranging from 22-gage sheet to 3-in. plate can be welded in a single pass. Material of any thickness can be welded by a suitable number of passes.

Speeds of about 200 in. per min can be used on thin material. The currents required vary with the material and are usually about six to ten times those used with the manual electric-arc welding methods. A maximum of about 4000 amp can be applied with the present equipment. This would be approximately the current required to weld plates 3 in. thick in a single pass.

Because of the nature of the process, welds must be made in a horizontal or nearly horizontal position. Such welds can be made without special plate-edge preparation in material less than $^{1}/_{2}$ in. thick. Thicker material is usually prepared with a single or double V. Single-pass butt welds are usually backed up by a copper strip or a layer of granular material pressed against the back of the weld. With this process, butt, fillet (positioned and nonpositioned), and plug welds can be made.

THERMIT WELDING. In the thermit welding process, superheated steel is obtained by the exothermic reaction which results when a mixture of iron oxide and aluminum is ignited. The iron oxide is reduced by the aluminum to iron. The resulting superheated steel is poured into a mold around the joint to be made, mold and joint having been preheated. The superheated steel resulting from the iron oxide aluminum reaction has a temperature far in excess of the melting point of steel, and hence there is sufficient heat to produce fusion with the surfaces of the parts to be joined. The composition of the metal may be varied by the introduction of alloying elements. The process has been applied to all types of wrought or cast steel and iron. It is particularly applicable to repair of heavy sections and for making butt welds in rails.

2. WELDING OF VARIOUS MATERIALS

STEELS. General. The difficulty which may be encountered in the welding of various steels is, in general, in proportion to the hardening developed in the heat-affected zone along the weld. With high hardness, underbead cracking may result from welding stresses.

As the carbon content of steel increases, the potential hardness increases, and the addition of alloying elements in general emphasizes the hardening effect.

Excessive hardening can be somewhat controlled by regulating the cooling rate from the welding temperature. With thermit welding and thermit-pressure welding, a slow cooling rate can be obtained by the insulating effect of the mold surrounding the entire weld. With gas welding, particularly on thin sections, the torch can be used to heat the base materials and keep the zone adjacent to the weld sufficiently hot to retard cooling. With arc welding the area of high temperature is very localized, and preheating of the parts is sometimes necessary to obtain slow cooling and to reduce welding stresses. With a composition giving high hardness, more difficulty is likely to occur with heavy sections, and preheating will be necessary in whatever welding method is used. Heating to 400 to 500 F is effective, and, depending on the steel and the particular structure, this temperature may need to be maintained until the weld has been post heat treated.

Variation in the quality of steel may result in welding difficulties even for grades normally considered weldable, such as plain carbon steels below 0.30% carbon. Fortunately, such difficulties are exceptional. No definite information on the reasons for such difficulties is available, although it is generally conceded that trouble may occur because of excessive segregation in the steel or because of the presence of abnormally large amounts of residual elements such as arsenic and copper. Laminations in rolled steel products will, of course, produce welding difficulties, especially if the lamination extends along the joint edge.

CASTINGS. Castings may be satisfactorily welded, provided rolled or forged steel parts of the same composition can be satisfactorily welded. This assumes that the casting adjacent to the weld region is sound and free from shrinkage cracks which otherwise would open under the contraction stresses during cooling from welding.

IRON AND CARBON STEELS UP TO 0.35% CARBON. Iron and plain carbon steels up to 0.35% carbon are readily welded by all processes, and completed welds can be obtained with strength equivalent to the base materials. Preheating is not necessary, except to reduce cracking in extremely rigid joints. In fusion welding, with gas or electric arc, filler metal of approximately 0.15% carbon is recommended. With shielded-arc methods (carbon or metal arc), ductile welds with strength of 60,000 to 70,000 psi are obtained. This strength can be increased to 70,000 to 80,000 psi, without loss of ductility, by small additions of alloying elements. Molybdenum in amounts of 0.2 to 0.4% is very effective.

Where stress relieving is required, heating at 1100 to 1200 F for a period of one hour per inch of thickness is recommended.

MEDIUM-CARBON STEELS OF 0.35 TO 0.60% CARBON. As the carbon content of steel increases above 0.35%, difficulty in welding is likely to develop. With thin sections and a flexible design, gas or arc welding may be used without preheating, but in joints over $^3/_8$ to $^1/_2$ in. thick, preheating is necessary. In oxygen-acetylene gas welding, better welds are obtained with a flame having excess acetylene. To develop equivalent strength in the weld a low-alloy filler metal should be used for both gas and arc welding methods. A rod containing chromium and molybdenum is recommended. These steels are readily welded by the thermit process.

Welds should be stress relieved at 1100 to 1200 F and, where preheating has been necessary or with the higher carbon ranges, this stress relieving should be carried out before permitting the weld to cool below 300 F.

HIGH-CARBON STEELS OF 0.60 TO 1.50% CARBON. Steels above 0.60% carbon may be welded quite satisfactorily by the thermit process, a method that has been used considerably for butt welds in rails. Gas and arc welding can be done only with considerable difficulty, and the resulting welds are only fairly satisfactory. Gas welding is more easily performed. A joint can be made by arc welding by depositing low-carbon metal over the surface of each part and then making the arc weld between these low-carbon surfaces. The resulting weld, of course, has the properties of a low-carbon weld.

LOW-ALLOY HIGH-YIELD-STRENGTH STRUCTURAL STEELS. There are a considerable number of low-alloy steels especially designed to produce yield-point values of 50,000 to 70,000 psi and with ultimate strengths of 70,000 to 100,000 psi. Most of these steels have been produced with a low carbon content, and no particular difficulty is encountered in welding them. In general, where carbon contents are 0.20% or less, gas or arc welding can be performed without preheating. With higher carbon contents, preheating will often be necessary. To develop weld strengths equivalent to the base material it is necessary to use filler metal with some alloy content. Low-carbon filler metal with alloy composition similar to the base materials usually can be used. Stress relieving should be carried out at 1100 to 1200 F.

SAE ALLOY STEELS. For welding of the SAE alloy steels, the same general procedure may be used as for the alloy structural steels. The ease of welding will depend on the hardness developed in the heated zone. Where high hardness occurs, preheating to 300 to 500 F will be necessary. Filler metal of similar alloy composition to the base material usually can be used.

CHROMIUM STEELS OF 4 TO 6% CHROMIUM are definitely air hardening, even with low carbon content, and preheating at 300 to 500 F is essential. Welds generally must be kept above 300 F until annealed or stress-relieved. Heat treatment after welding should be a full anneal or long-time stress relieving at 1300 to 1350 F. The same procedure should be used with steels of $2\frac{1}{2}$% chromium. With such procedure, welds in these steels with carbon less than 0.20% are very ductile and equal to the base metal in every respect.

CORROSION- AND HEAT-RESISTING STEELS have high percentages of chromium or chromium and nickel, with low carbon content. To weld steels with 12 to 30% chromium requires preheating to above 200 F and an annealing treatment after welding in order to obtain ductility. The lower chromium ranges, 12 to 16% chromium, may be welded without great difficulty if preheating precautions are taken. As the chromium content is increased, the welds are much less ductile, and the very high chromium range becomes very difficult to weld. Heat treatment should consist of annealing at 1450 to 1550 F. To maintain equivalent chromium content in the welds, filler metal should have a slightly higher chromium content than the base metal. Because of rapid carbon absorption in high-chromium steels, the carbon arc method is not suitable.

The stainless steels containing high percentages of both chromium and nickel are not subject to hardening from heat treatment and may be welded without difficulty. Typical steels of this group are 18% Cr-8% Ni, 25% Cr-12% Ni, 25% Cr-20% Ni; there are many other variations of analysis. Welds in all these materials are soft and ductile, and no heat treatment after welding is required, except as may be needed to improve corrosion resistance. In this respect the 18% Cr-8% Ni type is subject to serious loss of corrosion resistance, due to precipitation of carbides in the temperature range of 900 to 1500 F. For this reason, very low carbon contents (less than 0.07%) are desirable for these steels if they are to be welded. The carbides may be stabilized by addition of titanium or columbium, and steels so stabilized are recommended for welding. Filler metal also should be of the stabilized analysis. Titanium should be used in amounts at least six times the carbon content, and columbium in amounts at least ten times the carbon content. If the 18% Cr-8% Ni steels are not of the stabilized type, heat treatment after welding should consist of heating to 1900 to 2100 F, followed by rapid cooling. In the higher alloy steels, carbide precipitation is not serious.

Because of higher electrical resistance and lower heat conductivity, electric welding of these steels requires about 10% lower current than carbon steels. Also, the high coefficient of expansion requires additional care to prevent excessive distortion.

MANGANESE AUSTENITIC STEEL with 12 to 14% manganese and approximately 1 to $1\frac{1}{2}$% carbon is quite brittle in the as-cast condition, because of large carbide areas, but upon heating to 1900 F and quenching, the carbides are retained in solid solution and a tough ductile material results. On reheating to 1100 to 1400 F, carbides are again precipitated and the material becomes hard and brittle. In welding this steel it is necessary to deposit weld metal which is ductile and to avoid embrittlement of the base material by excessive heating.

Welding may be accomplished by either the gas or arc methods. A filler metal of 12 to 14% manganese and 3 to 5% nickel is recommended to obtain a good-quality weld. Care should be taken to avoid excessive heating of the base metal.

CAST IRON. Cast irons, either gray, white, or malleable, are not considered adaptable to welding, but may be welded with proper care and procedure. White cast iron is the most easily welded. The process may be the gas or metal arc, using a white cast-iron filler rod. Resistance welding may be used where shape permits. Gray or malleable castings may be fusion welded with proper precautions, and the same general procedure can be applied for both types of castings. Whatever method is used, because of the low tensile strength and poor ductility of these materials, it is essential to avoid excessive variations in temperature throughout the casting to prevent cracking from thermal stresses.

Gas welding is best performed by preheating the casting to approximately 1000 F and completing the weld while it is kept at that heat. After welding, the casting must be cooled slowly. A suitable flux such as borax should be used, and the filler metal should be of a high-silicon cast-iron composition. Welds made in this manner will be machinable.

Carbon arc welding can be performed in a manner similar to that used for gas welding. Use of cast-iron filler rod and borax flux is recommended.

Metallic arc welding may be performed using either coated cast-iron composition electrodes or coated steel electrodes. Preheating is necessary in using the cast-iron electrodes, and this method will produce a machinable weld. The method is best adapted for welding in the flat position. Using coated steel electrodes, welds may be made without preheating the casting, but a hard unmachinable zone will be present. Small-diameter electrodes ($^1/_8$ in. maximum) should be used, and welding should progress slowly with intermittent peening. This will keep thermal stresses in the casting, and contraction stresses in the weld metal, at a minimum. Welds made with steel electrodes will be considerably stronger than the cast-iron base metal. Welds not so strong, but very satisfactory and machinable, may be made, using an alloy electrode of high nickel composition such as Monel metal (68% Ni, 29% Cu). Similarly, welds may be made with copper or copper alloy filler metal.

ALUMINUM ALLOYS. Gas, elecric-arc, or electric-resistance welding may be used for joining aluminum alloys. Alloys suitable for welding are discussed in Section 4, Article 7.

MAGNESIUM ALLOYS. Details of welding techniques for magnesium alloys are discussed in Section 4, Article 15.

3. MECHANICAL PROPERTIES OF FUSION WELDS IN STEEL

CONDITIONS FOR SOUND WELDS. The physical properties of fusion welds depend, of course, on the relative freedom of the weld metal from such defects as porosity, entrapped slag, cracks, and incomplete fusion. Assuming that a sound weld has been obtained, physical properties depend on the degree of protection which has been given to the molten metal from the gases of the atmosphere. Avoidance of contamination by nitrogen and oxygen is especially important in metal arc welding. Welds deposited with bare wire electrodes with no arc protection will contain approximately 0.10 to 0.15% nitrogen and approximately 0.3% oxygen. With a satisfactorily designed covered electrode, the deposited weld metal will contain less than 0.03% nitrogen, with oxygen correspondingly low.

The tensile strength of steel welds may be considerably increased by addition of suitable alloying elements, but in all cases, for a given composition, superior properties are obtained in metal arc welding by using covered electrodes.

SOUNDNESS OF FUSION WELDS. Producing welds by the gas or arc fusion processes introduces many variables of technique and operator skill which may cause mechanical defects in the weld. These may be gas pockets, entrapped slag from the electrode covering, zones of incomplete fusion between weld metal and base material, or cracks resulting from contraction stresses.

Several methods have been utilized for inspection of welds to detect such defects. The common medical stethoscope has been used to a limited extent, by detecting variation in sound issued at positions along the welds when struck by a hammer. This method is not very sensitive and is limited to welds up to about 1 in. thick. Magnetic methods have been used quite successfully in magnetic materials, to detect cracks at or near the surface of welds. They have not proved adaptable to detect defects far below the surface. The simplest of the magnetic methods consists of establishing a magnetic field approximately perpendicular to suspected defects and dusting a magnetic powder over the surface. The powder tends to concentrate at locations of fissures or cracks. The magnetic method may be used to advantage in some cases to supplement radiographic methods for the detection of small surface cracks which cannot be disclosed readily by the x-ray method. The magnetic method also may be used to advantage for examining welds which cannot for one reason or another be x-rayed.

The most thorough and reliable method of inspection is x-ray examination of the complete weld. The x-ray tube is placed on one side of the weld and photographic film on the opposite side. Radiographs of excellent quality can be obtained which register the presence of all types of defects and give a clear picture of their size, location, and distribution. This method may be used for examination of steel sections 4 $^1/_2$ to 5 in. thick, and will detect defective areas that are in thickness equal to 2% or more of the steel section. Gamma rays emanating from radioactive materials may be used in the same manner as x-rays. They are particularly applicable to heavy sections and to use in locations where x-ray equipment cannot be placed. Use of both x-rays and gamma rays requires suitable precautions to avoid excessive exposure of personnel to the radiation. See X-ray protection (*U. S. Bureau of Standards Handbook* HB20) for recommended practice.

STRESSES IN WELDS. The thermal contraction in a welded structure produces residual stresses in the welds. If the structure is sufficiently rigid, the stresses may become triaxial and of high magnitude. The residual welding stresses are somewhat reduced by preheating and may be virtually eliminated by postheating the entire structure to 1100 to 1200 F (if steel) for one hour per inch of thickness. If it is possible to heat only part of the structure at a time, the temperature gradient between heated and unheated portions should not exceed 200 F per foot.

The postheat treatment not only reduces the residual stresses but also produces desirable metallurgical changes, particularly in the heat-affected areas, which improve the mechanical performance of the welded structure.

Tendency to crack, particularly when welding a highly restrained structure, can sometimes be reduced by preheating or peening the intermediate passes.

Shrinkage of the welded structure may produce distortion. By control of procedure, distortion may be reduced considerably. Peening the weld metal also is of assistance in controlling distortion.

4. WELDING DESIGN

ADVANTAGES OF WELDED CONSTRUCTION. The design and assembly of a structure with welded connections offer a number of advantages as compared to mechanical joints, such as riveting. The connections are simplified in that the joint generally is made direct, and no third member, as a butt strap, is required. Welded joints permit placing the added metal exactly where needed, and produce an integral structure which, with mild steel, can develop 100% joint efficiency on any thickness of section. Elimination of extra material results in a weight saving of up to 25%. This saving in weight is an important consideration in transportation fields.

FIG. 1. Forms of joints for fusion welding.

FORMS OF WELDED JOINTS. Many forms of joints are used in fusion welding processes. Some of the more widely used are shown in Fig. 1. Drawings of welded construction should contain full information on weld details, type of joint, dimensions of welds, etc. The American Welding Society has adopted welding symbols which may be conveniently used on drawings specifying welding. In designing a welded structure, consideration also should be given to the following points:

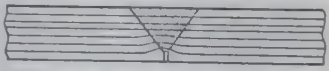
(1) The joint should be made as accessible as possible to the welding operator. This means that wherever possible welding should be done in the downhand position rather than taxing the skill of the operator by welding in an overhead position.

(2) The dimensions of the joint should be such as to permit complete fusion through the thickness of the sections being welded. If incomplete fusion is obtained, an undesirable stress concentration will result. (See Fig. 2.)

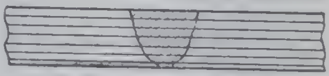
(3) Butt joints are preferable from the viewpoint of uniform stress distribution across the weld. In the case of fillet welds a 30–60-degree weld provides a more uniform transfer of stress through the weld than a 45-45-degree weld.

(4) Where the structure previously has been a casting or built by riveting, and where the structure is being redesigned for welded construction, it should be appreciated that welding cannot be used interchangeably with the older riveted or casting design, and the designer should adapt his structure as far as possible to utilize the full advantages of welded construction.

(5) Where distortion of the welded structure by reason of the contraction of the weld metal is likely to occur, and where the distortion is objectionable, the welds should, if possible, be so positioned that the contraction of the welds will tend to balance each other on each side of some central plane through the structure.



Undesirable stress concentration with incomplete fusion



Uniform stress distribution with butt joint

FIG. 2. Stress distribution in welds with incomplete and complete fusion.

The design stresses will, of course, vary, depending on the quality of the welds and the conditions of service of the structure. For example, pressure vessels may be built on the basis of factors of safety of 4 or 5, corresponding to an allowable working stress of about 10,000 to 12,000 psi (55,000 psi tensile strength steel), while an open storage tank could reasonably employ much higher stresses. The allowable working stresses for welds of various types have been set by engineering codes governing different types of construction.

A list of the commonly used construction codes is given below:

ASME Boiler Construction Code, Section I, Power Boilers.
ASME Boiler Construction Code, Section III, Locomotive Boilers.
ASME Boiler Construction Code, Section IV, Heating Boilers.
ASME Boiler Construction Code, Section V, Miniature Boilers.
ASME Boiler Construction Code, Section VIII, Unfired Pressure Vessels.
ASME Boiler Construction Code, Section IX, Qualification of Welding Operators.
API-ASME Code for Unfired Pressure Vessels.
Office of Merchant Marine Safety, U. S. Coast Guard.
Bureau of Ships, U. S. Navy Department.
ASA Pressure Piping Code.
National Board Rules for Repairs by Fusion Welding.

Some of the constructional codes issued by the American Welding Society are: Code for Fusion Welding and Gas Cutting in Building Construction (*J. Am. Welding Soc.*, March 1935); Specification for the Design, Construction, Alteration and Repair of Railway and Highway Bridges; Tentative Code for Fusion Welding and Flame Cutting in Machinery Construction; Marine Code for Welding and Gas Cutting, Part D, Rules for the Fusion Welding of Hulls and Hull Parts (*J. Am. Welding Soc.*, Feb. 1935).

5. FACING OR SURFACING BY WELDING

Facing or hard-surfacing is a process of welding onto a wearing part a layer, edge, or point of a metal that is resistant to abrasion or corrosion. Hard-facing has proved to be an easy and economical means of keeping equipment in good operating condition. There are also soft-surfacing operations—for example, the application of a bronze bearing metal.

HARD-FACING. Hard-facing, applied originally to metal-working dies, oil-well drilling tools, and excavating equipment has numerous other applications. No single grade of hard-facing material is suitable for all applications. To secure hardness, toughness, resistance to shock, resistance to corrosion, and other desired qualities, alloys of widely different compositions have been developed. They may be classified in five groups.

(1) Alloy Steels That Contain Less Than 20% of Alloying Elements. Alloying elements used are mainly chromium, tungsten, manganese, silicon, and carbon. Although not so hard as higher-priced hard-facing metals, alloy steels of this group possess greater toughness and resistance to shock. They have much greater resistance to wear than low-carbon steels, and some compare favorably with Hadfield's high-manganese steel in this respect.

(2) Ferrous Alloys That Contain More Than 20% of Alloying Elements. Chromium, tungsten, manganese, silicon, carbon, and sometimes cobalt, nickel, and other elements are used in these alloys. High hardness and greater resistance to abrasion insure longer service for alloys of this group. As a result, they are not so tough or resistant to shock as alloys of Group 1, but are particularly well adapted for use as the final wear-resisting surface, after the worn part has been built up with high-strength welding rod.

(3) Nonferrous Alloys. Cobalt-chromium-tungsten alloys are available in several grades, all highly resistant to wear and corrosion. Many of them retain their original hardness virtually unimpaired at elevated temperatures.

A newer development is the use of nickel-base alloys (Hastelloys) for the facing of parts subjected to severe chemical corrosion. This type of alloy combines outstanding resistance to corrosion with excellent mechanical properties, some grades being comparable to high-strength steels in tensile properties. Some grades will also take a high polish and retain it even when subjected to severe atmospheric and chemical corrosion.

(4) So-called Diamond Substitutes. These are the hardest and most wear resistant of all hard-facing materials. Some are almost pure tungsten carbide; others contain 90 to 95% tungsten carbide with the remainder cobalt, nickel, iron, or similar elements. Some materials contain boron compounds or tantalum carbide. The alloying elements are added to impart toughness and impact strength to the tungsten carbides; the hardness, however, is slightly reduced as a result.

The diamond substitutes, furnished in the form of small castings, are embedded in the cutting and wearing surfaces of oil-well drilling bits and similar tools. Tungsten carbide inserts are not melted or damaged to any appreciable extent in the usual method of application by the oxyacetylene process. The process of applying tungsten carbide shapes to wearing surfaces is known as *hard-setting*. After hard-setting, the entire wearing surface usually is hard-faced, which produces a composite material that has excellent resistance to abrasion with maximum cutting qualities at edges.

(5) Crushed Tungsten Carbides of Various Screen Sizes. These are furnished packed in steel tubes, fused to steel strips, or bonded with steel as a composite rod. Both tubes and strips come in short lengths, which are applied like ordinary welding rods. Grains of crushed tungsten carbide are also supplied loose for application with a Haystellite powder dispenser.

HARD-FACING PROCEDURE. Although hard-facing materials can be applied by any standard fusion-welding method, certain factors govern the choice of method for any specific applications: (1) base material to be faced, (2) hard-facing material selected, (3) size, shape, and thickness of base material and deposited facing materials, (4) initial cost of equipment and facing material, (5) smoothness of deposits, (6) overall cost, and (7) quality and appearance of deposits.

Use of the oxyacetylene blowpipe allows close control of the operation, produces a smooth deposit, insures easy elimination of particles of scale and foreign matter and easy forming of edges and corners. Although arc welding is not so flexible as gas welding, the resultant deposits are of good quality. The metal arc welding process is particularly suitable for use on thick base metals where thin, smooth deposits are not required. Another advantage is that only a small amount of distortion is produced in hard-facing large steel castings and similar heavy parts because the heat from the arc is localized.

Loose scale, dirt, rust, or other foreign substances should be removed from the area to be hard-faced, preferably by grinding or machining. When the hard-facing material is to be applied in a groove, corner, or recess, it is desirable to have all corners well rounded. If only a small area is to be hard-faced, a suitable shallow recess or indentation may be prepared for receiving the hard-facing metal.

THICKNESS OF HARD-FACING DEPOSIT. The proper thickness of deposit depends on the specific application, but usually ranges from $^1/_{16}$ to $^1/_4$ in.; the average is approximately $^1/_8$ in. Usually, however, a part that requires a deposit thicker than $^1/_4$ in. should be rebuilt before hard-facing to within $^1/_{16}$ to $^1/_4$ in. of the finished size. For this purpose an alloy of Group 1 should be used, or material similar to the base metal. The final hard-facing deposit is applied thick enough for grinding to finished size.

BRAZING

By Samuel Damon

Brazing is the joining of similar or dissimilar metals with a filler metal or alloy of lower melting point than that of the metals joined. Sometimes referred to as hard soldering, brazing involves joining or filler metal having a melting point in excess of 1100 F. Soft soldering involves filler metal which melts below 600 F (see p. 4-84).

Essential requirements of a brazing metal or alloy are high fluidity and ability to "wet" or alloy with the metals to be joined when at the brazing temperature. In respect to wetting, both the metals joined and the molten brazing material must be free from oxides upon attaining the brazing temperature. The accomplishment of this requires (1) a reducing atmosphere; (2) the addition of flux to the joint; or (3) the exclusion of oxygen during heating by immersion in a molten bath.

Copper brazing, a comparative newcomer to the field, is limited largely to furnaces containing controlled reducing atmospheres. However, recent developments in high-temperature salt baths have made available a new heating medium; in some cases induction heating has been applied using either a flux or a reducing atmosphere to prevent oxidation.

Silver brazing, in which all types of heating are applicable, is widely utilized. Flux is employed in every case unless a protective atmosphere, such as is used in furnace brazing, makes possible the complete prevention of oxide formation.

GENERAL CONSIDERATIONS. Brazing has many advantages over other joining methods for certain applications. High strength, high resistance to vibration and impact, and a strong bond in high-temperature service are among these advantages. This is particularly true of copper-brazed assemblies. Because of the slight clearances used and the deep penetration into the joint obtained with these alloys, the production of pressure-tight joints is assured. Usually a mere visual examination after brazing is sufficient to establish this.

Concomitant properties of such joints are high thermal and electrical conductivity. Distortion and residual stress build-up due to the high temperatures obtained locally, as occurs in welding, is not a serious drawback in torch or induction brazing because of the comparatively low temperatures involved. Where methods such as furnace heating are utilized, with attendant uniform heating and cooling, distortion and stress concentrations are practically eliminated.

Owing to the feasibility of building up brazed shapes by proper design, many new possibilities in fabrication are opened. This is especially true in furnace brazing where a number of joints can be brazed simultaneously.

A further advantage which may be gained from using furnace or salt-bath brazing is the bonding and simultaneous hardening of steels, especially those of the air-hardening type. This becomes particularly important if the treatment is carried out in an atmosphere or bath designed to prevent decarburization, as the part can then be completely machined and assembled before brazing and can emerge after brazing as a completely finished and hardened tool ready for use, with only tempering required. An additional factor favoring the use of protective atmospheres is the clean, bright surface resulting. Much saving in cleaning and pickling expense is thus assured.

Perhaps the most distinct benefit of the brazing technique, however, is the high production rate inherently possible. Where mass production is a necessity, brazing, especially by furnace or induction heating, has become an essential tool of industry.

6. BRAZING METHODS

TORCH BRAZING. Hand or torch brazing, the best-known method, is widely employed in industry. The work is assembled after cleaning and fluxing and, if necessary, is supported in a fixture. Heating is accomplished by playing a torch flame, which may be oxyacetylene, oxyhydrogen, or even air-acetylene or air-gas, maintained on the reducing side, onto the assembly at a point near the joint to be bonded and, where possible, on the more massive member or the material of higher heat conductivity in the assembly. The torch flame is moved constantly to prevent local overheating and is not allowed to impinge too long upon the flux or silver solder. Usually insulating brick is used on the work table to retain the heat around the work, thus enabling more rapid heating. When the joint area is at temperature as judged by eye, the brazing alloy is fed into the joint. The alloy melts and is drawn into the opening by capillary attraction until the joint itself is completely filled, after which the molten alloy forms a fillet on the outside of the joint.

This method requires skilled operators, and although slow as compared to other brazing methods it is widely used because of the low cost of the equipment and its versatility.

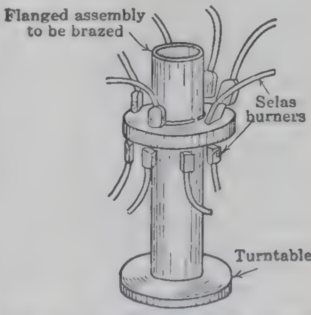


Fig. 1. Typical setup for brazing with gas burners.

GAS BURNER BRAZING. Arrangements for automatic torch brazing have been introduced which utilize gas burners (Fig. 1) set in suitable relationship to the work. The work to be brazed is held on a conveyor and carried into and held within the range of the flames from the burners for a predetermined interval of time. The work then moves away from the hot burners and the next set-up moves into the brazing position. For circular joints the fixture may be one that rotates the work while it is in the hot zone until brazing is accomplished and then moves it out to cool. This technique enables high production since the rate of heating with these gas burners is high, and, once the positioning of the burners and the time cycle have been determined, the brazing operation can be performed automatically with unskilled personnel handling the set-up of the assemblies.

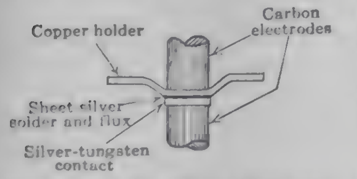

Fig. 2. Method used for silver brazing contacts by resistance heating.

RESISTANCE BRAZING. As indicated by the name, direct electrical resistance heating such as obtained in a spot or butt welder is used to join the parts. The members are placed between the carbon or molybdenum electrodes of the welding machine with brazing alloy and flux in the joint. The current is then applied until the filler metal melts and flows. (See Fig. 2.)

This method can be very rapid but is limited to assemblies which lend themselves to mounting in such a machine.

CARBON RESISTANCE BRAZING is similar to the electrical resistance brazing method except that carbon electrodes are heated by the current, and the heat is transferred to the work by direct conduction and some radiation. The work is similarly set up, with the brazing material usually in foil form inside the joint. The current is then applied until the filler metal flows freely. In this and the resistance brazing method, pressure as well as heat is applied to the joint to make for good cohesion.

SALT-BATH BRAZING. Molten salt baths, usually neutral in character (although fluxing agents can be included to dissolve oxides), are well suited to brazing of assemblies which are of appropriate dimensions and shape. The part is fluxed, if necessary, to prevent oxidation, and the silver alloy is placed at or in the joints. After the flux is completely dry, to avoid the danger of an explosion if wet flux is introduced into the pot, the assembly in a suitable jig or hanger is immersed in the molten salt far enough to cover entirely the joint region. The salt bath is maintained at a temperature somewhat higher than the top of the melting range of the brazing material, and, therefore, the operator is assured that the alloy has fused and flowed into the joint when the assembly arrives at the bath temperature. (See Fig. 3.)

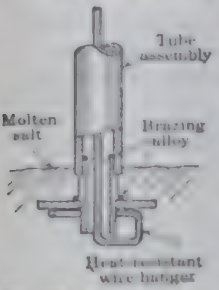

FIG. 3. Brazing in a molten salt bath.

This method has added advantages in that temperature is controlled and carburization or decarburization as well as oxidation can be completely eliminated, especially in steel pieces.

ATMOSPHERE FURNACE BRAZING. The most versatile of brazing methods, this fashion of joining metals is also ideally suited to mass production of brazed articles. The process is most widely applied in copper brazing and is also extensively utilized in silver solder brazing.

The equipment in the pusher-type furnace consists of a gastight furnace, with a cooling chamber, also gastight, separated from the heated region by an externally operated door, and with close-fitting doors at the front entrance into the hot zone and at the rear exit from the cooling chamber. (See Fig. 4.) In the conveyor-type furnaces, purging chambers at the front and rear are used, and doors are adjusted to allow just enough room for entrance of the particular assembly being joined.

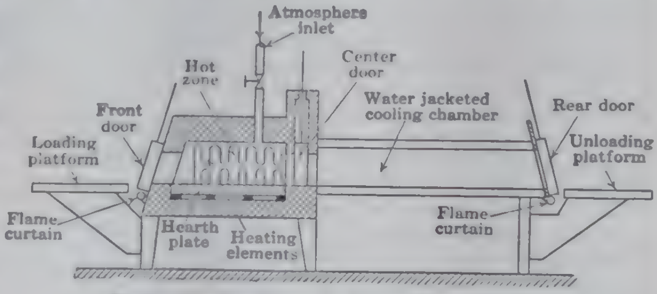

FIG. 4. Section through a pusher type furnace.

A reducing atmosphere produced in a special generator, or consisting of hydrogen or dissociated ammonia, is fed into the furnace and cooling chamber to maintain a constant pressure inside the furnace against the ingress of contaminating air or water vapor. The formation of oxides is inhibited and oxides present upon entering the hot zone are reduced, thus permitting the molten brazing metal to flow smoothly through the joint and uniformly wet the surfaces to be joined.

The same general technique previously described for the set-up of the articles to be brazed is pertinent. In copper brazing no flux is used unless the steels being joined happen to be high in alloys such as chromium, aluminum, or manganese. In silver brazing, flux is generally applied unless the components of the article consist of materials, such as copper, silver, or nickel, whose oxides are easily reduced in the furnace atmosphere, and the brazing alloy contains no zinc or cadmium.

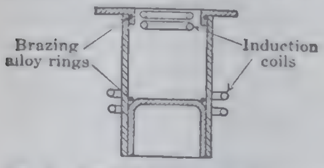

FIG. 5. Typical setup using internal and external coils in the induction brazing of a tube assembly.

INDUCTION BRAZING. Heat generated as a product of the resistance of metals to eddy currents induced within them by high-frequency currents passing through adjacent coils has gained wide acceptance as a means of treating metals. This induction brazing is likewise becoming an important tool in the high-production brazing of assemblies. (See Fig. 5.)

Where shape and size are favorable, the use of indexing tables or conveyer belts and suitable coils gives extremely rapid joining. At present, however, this mode of brazing is limited mainly to silver brazing jobs because of the objectionable oxidation and the difficulty of obtaining satisfactory bonds in copper brazing. This is solely a result of the longer time required to heat to the higher temperature required to melt copper; in some specific applications the use of chambers filled with a reducing atmosphere has overcome this difficulty.

Since the heat is generated within a shallow skin at the surface of the joint, extremely rapid heating and flow of the filler metal to bond the joint is obtained, with little change in the parent metal.

7. APPLICATION OF BRAZING

PLAIN CARBON STEELS. All ordinary steels of the plain carbon or low-alloy type are readily brazed with either copper or silver alloys. Furnace copper brazing is most commonly applied here, as the atmospheres used are reducing to any oxides present on the surface of the steel or in the copper brazing material itself, thus eliminating flux as a requirement. Steel is readily wet by molten copper in the absence of any oxides, and the joints in the assembly are quickly penetrated. Usually the time in the furnace is limited to that required to heat the assembly to at least the melting point of the brazing material, after which the assembly is introduced into the cooling chamber where also a protective atmosphere is maintained. After sufficient cooling time is allowed, the parts can be removed into the air and are found to have an extremely bright, clean surface.

ALLOY STEELS. As the alloy content of the steel increases, particularly in chromium, silicon, or aluminum, the ability to copper-braze without flux is lessened unless atmospheres of high purity such as dry hydrogen are used. Since the purity of the atmosphere in the furnace is the criterion of its value, it becomes necessary to use muffle-type furnaces when the high-alloy steels are to be brazed, to obtain the necessary freedom from contaminating gases. Usually the added problem of prevention of decarburization, and sometimes carburization, must be overcome with these steels. However, these difficulties are not met in other forms of heating, as by torch or induction, and frequently such methods are employed with great success in the brazing of nitriding or stainless steels. The brazing material used is one of the silver solders, and flux is always necessary.

Attention must be given to the need for further heat treatment which may exist, and, if such is the case, brazing alloys of sufficiently high melting ranges should be employed to forestall the occurrence of melting of the joint material during the subsequent heat treatment.

SURFACE PREPARATION. Some thought must be given also to the surface most desirable for purposes of wetting and bonding. A smooth, highly polished surface is not conducive to creeping of the molten brazing material because of the failure of the surface attraction of the metal to overcome the surface tension of the liquid copper or silver alloy. On the other hand, a clean, slightly roughened surface such as that obtained by shot blasting, pickling, or machining will result in rapid and uniform flow of the brazing metal over the surface of the steels. Judicious use of this type of surface inhibits excessive flow of the joining material where this is of importance.

CONTROL OF FLOW. Other methods for preventing undue flow of the material involve the use of grooves or ledges at appropriate points, the embedding of the brazing alloy in grooves concealed in the joint, a decrease of the hydrogen content of the atmosphere, or the use of the minimum amount of brazing material compatible with the good quality of the brazed joint.

Another method employed with success is the painting on of refractory powders such as chromium oxide, magnesium oxide, or aluminum oxide in the form of thin paste to act as barriers to the undesirable spread of the liquid braze metal. Where localized heating such as induction, torch, dip, or resistance can be used, the problem of unwanted flow away from the joint is less troublesome if due care is exercised in the application of heat to the joint.

Since a forged surface is highly conducive to superfluous creep and such surfaces are frequently involved as parts of assemblies, it is sometimes found advisable to postpone the steps to control the amount of excess brazing alloy until after the brazing cycle. The system used then is removal of the excess material by grinding or scraping or by chemical or electrolytic stripping. Where copper is involved, either sodium cyanide or chromic acid solutions are effective stripping agents.

CAST IRON. The most common practice in brazing cast irons is the application of heat by torch or induction to the metal adjacent to the joint after proper preparation of the surfaces and fluxing. When the assembly has reached a temperature at or above the lower melting point of the brazing alloy, the alloy, usually in wire form, is fed into the joint until a fillet of metal is formed around the joint. Cast iron is not as easily wet as ordinary steels, and fluxes containing fluorides are usually required, especially when the iron contains alloys such as silicon, chromium, or manganese in percentages higher than those normally found in gray cast iron.

It is possible and in some cases is the manufacturing procedure to copper-braze in reducing atmospheres assemblies made up completely or in part of gray or malleable iron.

This is done in the complete absence of flux since the atmosphere maintained in the furnace acts to suppress the formation of oxides, and it is necessary only to assure good contact and clean mating surfaces at assembly. Where poor wetting is encountered in either copper or silver brazing of this material due to high alloy content it is sometimes possible to pretreat the surface by some such method as the Kolene bath treatment to reduce the alloy content at the surface, thus implementing the action of the atmosphere or flux and achieving satisfactory brazing.

Caution must be exercised in copper-brazing of cast irons because of their low melting point and the attendant danger of injury to assemblies by exposure to high temperatures due to a lack of accurate control. Furthermore, there is a definite tendency for growth in irons when treated at brazing temperatures, although allowance can be made for this in the design of joints if it is not otherwise detrimental.

COPPER-BASE ALLOYS. Copper and its alloys, such as brass and bronze, are confined to the silver brazing category because of the limits imposed by their melting points. Since, however, copper and brass are readily wet and bond well with either the silver solders or the phosphorus-copper brazing alloys, extensive application is made of this joining method. Practically any means of heating can be employed but the most common are torch, furnace, or induction heating. Flux is required for either brass or copper when the process used does not include a protective atmosphere. By using a reducing atmosphere, such as in furnace brazing, it becomes possible to use a brazing technique which does away with the need for flux. This involves the use of an alloy brazing material which contains neither zinc nor cadmium; copper plating of the brass or bronze components permits the fluxless brazing of these metals, inasmuch as copper will not oxidize in a reducing atmosphere and will wet freely with the filler metal, while the easily oxidizable offenders (zinc and cadmium) are not present.

Ordinarily the aluminum bronzes are brazed only with fluxes high in fluoride content, owing to the refractory character of the aluminum oxide formed during heating. However, these bronzes can be brazed with much greater ease with ordinary flux in torch brazing or even without flux in atmosphere-furnace brazing by the method outlined above. This method of brazing is also open to the use of the phosphorus-copper brazing alloys with equal facility. A precaution, however, is necessary with these alloys. They cannot be used in the brazing of assemblies made up in part of ferrous materials unless there is no possibility of the molten phosphorus-copper alloy contacting the ferrous portion of the structure. This care is required because of the alloying effect which takes place between iron and phosphorus, resulting in a weak, brittle iron phosphide compound which detracts seriously from the strength of the bond.

The application of atmospheres to furnace brazing of copper itself is confined to those containing a minimum of hydrogen and carbon monoxide, for unless the copper is oxygen-free some hydrogen embrittlement will occur from brazing treatments in atmospheres wherein these reducing gases are present. This is not, however, a great drawback where the mass of the copper assembly is such as to obviate the danger of bending failure.

NICKEL ALLOYS. When the assemblies are made up of parts with melting points well above that of copper (such as nickel or its alloys with copper, chromium, etc.), copper brazing furnishes consistently satisfactory brazed joints. With nickel or Monel no flux is necessary if a sufficiently reducing atmosphere is employed. The nickel-chromium alloys require flux unless special steps are taken to provide a pure dry hydrogen or dissociated ammonia atmosphere. These steps would include the use of gastight muffle furnaces and close control of the atmosphere to assure maintenance of an adequately low dew point. Silver solder is applicable to the brazing of the nickel-chromium alloys as long as sufficiently active fluxes are used. In the silver brazing of Monel, use of any of the solders melting above 1400 F is not recommended because of the occurrence of intergranular attack by the silver above this temperature. However, those melting below 1400 F are very successfully employed to obtain high-strength bonds in Monel. The phosphorus-copper brazing alloys are here again ruled out because of an embrittling effect ascribed to the phosphorus.

HARD INSERTS. Extended use is being made of the brazing process for joining tungsten carbide, stellite, etc., to steel in the manufacture of cutting tools, dies, punches, etc. Both silver and copper brazing are employed, and all the means of heating such as furnaces, torch, and induction have been found useful in the varied applications which arise. The method of simultaneous brazing and heat treatment is here also brought into play where the steel parts brazed to the insert consist of air-hardening tool steels. Flux is called for unless sufficiently reducing atmospheres are within reach.

ALUMINUM ALLOYS. With the advent of specially developed fluxes and filler materials, the brazing of aluminum is a commercial process. The filler material consists of a silicon-aluminum alloy slightly lower in melting point than the aluminum parts to be joined. The methods adopted in production include torch, furnace, and flux bath treatments. Very careful temperature control is required because of the slight difference in the melting points of the filler metal and the aluminum assembly. The joint obtained is fully as strong as similar joints which have been welded, and appearance is good because of the similarity in color of the brazing material and the aluminum. (See also Section 4, Article 7.)

STRENGTH. For low-carbon low-alloy steel, when the parts to be brazed are sufficient in mass to prevent changes in clearance during the brazing cycle, it is found that the shear strength of the joint decreases as the clearance increases. Figure 6 gives average values to be expected for fits usually employed. These values are for copper-brazed joints, and it is obvious that the recommended fit would be one of no greater than 0.001 in. clearance to 0.002 in. interference. It must be noted, however, that where higher strength steels are employed and where these steels have been hardened and tempered, the values are much higher, averaging 55,000 psi in shear when clearance is within the limits specified.

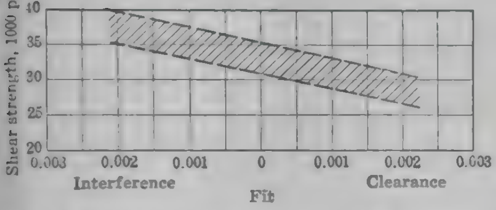

FIG. 6. Shear strength versus clearance for copper-brazed joints.

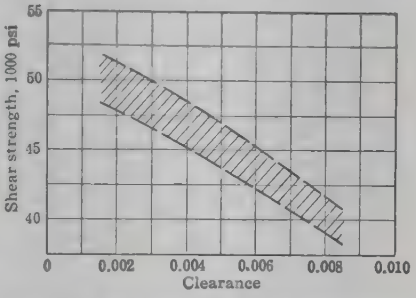

FIG. 7. Shear strength versus clearance for silver-brazed AISI E 4337 steel.

Because of the lower fluidity of silver alloys at the brazing temperature. interference fits are not recommended. However, even with the prescribed clearance of 0.001 to 0.003 in., the shear strength values of silver brazed joints are quite high, being between 24,000 and 40,000 psi with the higher value coinciding with the lesser clearance. (See Fig. 7.)

Generally it can be said that the tensile strength of a brazed joint is approximately twice the shear strength. Figure 8 gives average values to show what tensile strengths can be expected. Tensile strength also is found to increase as the strength of the parent material is increased and to vary inversely as the clearance.

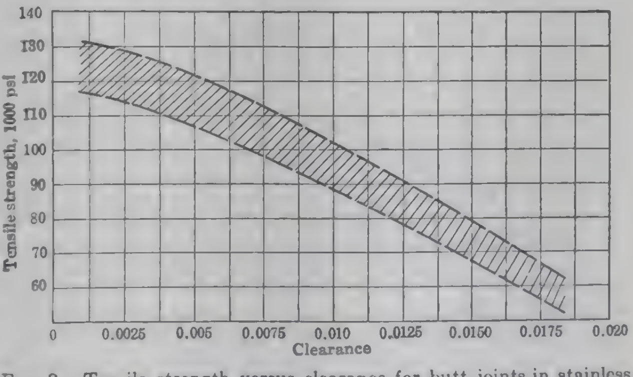

FIG. 8. Tensile strength versus clearance for butt joints in stainless steel of 160,000 psi tensile strength.

8. JOINING REQUIREMENTS AND JOINT DESIGN

In all brazing methods two factors, cleanliness and proper positioning of the individual parts of an assembly, must be given prime consideration.

SURFACE PREPARATION. Prior removal of oxides, dirt, grease, and oil is essential in assuring complete cohesion and penetration of the brazing material throughout the joint. If flux is used as a protection against oxidation during heating, its action is then more effectively applied to the work of preventing access of oxidizing constituents of the atmosphere to the surfaces of the joint. Conversely, if the protective medium is a reducing atmosphere, the work required of the atmosphere in curtailing oxidation of the joint area is lessened, and its effectiveness in reducing oxides already present is enhanced.

Mechanical elimination of oxides and tarnish can be carried out prior to brazing by filing, grinding, tumbling, shot blasting, sand blasting, or wire brushing. The last two are not highly recommended. In sand-blasting there is a tendency toward surface retention of particles of sand which later interfere with the flow of brazing material; in wire brushing there is the possibility of smearing metal over the oxide, rather than clean removal. A second well known method, pickling, is at times employed when, for some reason, a clean machined surface is not present.

Removal of grease and oil is carried out by thorough degreasing in an efficient solvent. This is important as during the rapid heating of the joint area the grease or oil is not usually burned entirely away but leaves a carbonaceous residue which may interfere seriously with the flow of the brazing alloy.

FIG. 9. Methods of positioning assemblies for brazing.

POSITIONING. In order to preserve correct alignment and relationship between the individual parts of an assembly during bonding, many devices are called into play. Among the fits which are self-aligning, the simplest might be considered the one maintained by gravity. Positioning is here attained by the use of protuberances or grooves in one or all of the parts or by utilizing loose pins or even by specially designed fixtures. (See Fig. 9.)

In respect to fixturing it must be remembered that if parts of the fixture are placed so as to be in direct line with the flame in torch brazing, or if the jig must be heated with the work as in furnace or possibly molten bath brazing, the fixture material must be heat resistant and must also resist wetting by the brazing alloys involved. Furthermore, it may be necessary to select a material with a rate of expansion and contraction suitable for the assembly so as to obtain dimensional accuracy. Many materials are available such as carbon or the stainless steels, and various rates of expansion and contraction can be selected from the alloys of chromium. If a particular thickness of brazing alloy is desired in a gravity assembly, it can be managed by the use of shims of the desired thickness which themselves should consist of a material readily wet by the brazing alloy but not dissolved by it.

In adding the brazing materials, it may be convenient to use brazing alloy in sheet form preplaced inside the joint or in wire form laid along the outer edge of the joint. If torch brazing is involved the alloy may be fed into the joint after the work attains the brazing temperature. At times, it will be found convenient to bury the filler material in cavities within the joint so that when the assembly is at brazing temperature the molten alloy will be drawn from this reservoir into the joint by capillary attraction. If the cavity method is used, particularly in furnace brazing, care must be exercised to provide vent holes to prevent entrapment of air within the reservoir.

A much-employed manner of joining is what might be called the pin or tube and hole type. (See Fig. 10, *a*, *b*, *c*, *d*.) Usually, simply making the parts a slight press fit preserves the positioning. If desired, it is quite feasible to apply a straight knurl to the male piece, thus avoiding the maintenance of close tolerances which might be objectionable from a cost or material standpoint. Other available means are peening of the hole or the pin and staking, swaging, or hot or cold riveting of the pin.

Of course, any of these methods can be adapted to positioning of tubes or bushings, and, in addition, such assemblies might profitably be spun, crimped, or expanded into place to accomplish the necessary dimensional control. Quite often it is simpler to design the male member of this type of assembly with a shoulder, thus automatically removing the positioning difficulty. A minimum fillet at the base of the shoulder and no countersink on the hole are then design requirements to prevent stoppage of the molten filler metal.

Oftentimes tack welding may be called into use or, if the thickness of the material is within limits, spot welding may be employed. The older methods of joining such as screwing, pinning, or riveting, at one time used alone, are also occasionally used where conditions so indicate.

In brazing of sheet metal assemblies, lap or interlocking joints are frequently employed, and usually the type of joint provides all the positioning necessary. If this is not the case, simply spot welding, peening, or sometimes screwing may be applied. (See Fig. 10*e*.)

Ordinary means such as described above for preserving alignment are, practically speaking, sufficient to carry out the joining of most assemblies. Nevertheless, it sometimes occurs in furnace brazing, for instance, that the most satisfactory method available may consist of simply holding the positioning of the parts by use of some material such as cellophane tape, wood, or perhaps lacquer until they are placed in the hot zone of the furnace, and then, after sufficient time has been allowed for brazing the assembly, cooling with the furnace to below the freezing point of the brazing material before introducing the assembly into the cooling chamber. Another means of resolving assembly difficulties may be the brazing of subassemblies with the higher-melting-point filler metals followed by a joining of these brazed subassemblies into a final assembly using one of the lower-melting-point brazing alloys.

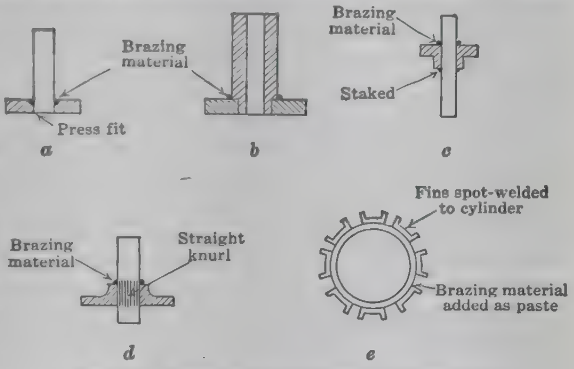

FIG. 10. Examples of positioning by simple fit.

9. BRAZING-ALLOY SELECTION

A point which demands consideration is the type of alloy to be used as a filler metal as well as its form and placement in the assembly. The choice of alloy depends on factors such as its melting point compared to that of the assembly components and the absence of any materials in the alloy which might have a harmful effect on the members of the assembly; i.e., phosphorus combining with iron to form phosphide and the intergranular penetration of silver into some nickel alloys creating an embrittling effect. Table 1 gives the analysis and melting range for some commonly employed brazing materials. Other alloys are listed in Table 2, page 4-85.

With these points in mind, the selection of the alloy is carried out. The form in which it is to be used and whether it shall be preplaced or fed into the joint are determined by such considerations as (1) whether the part is to be torch-brazed where feeding is possible or furnace-brazed where it is not; (2) whether counterbores or concealed grooves or cavities are permissible in the assembly, in which case wire, sheet, or slugs of brazing material can be used; (3) whether the flow of the alloy into the joint will be aided by gravity or whether capillary attraction is solely depended upon. If it is difficult to place the alloy where wanted, applying pastes made from the powdered brazing metal, or plating with the brazing metal, or even spraying the metal onto the desired location offer alternative methods.

Table 1. Commonly Used Brazing Alloys

Designation	Composition, %					Melting Range
	Cu	Ag	Zn	Cd	P	
Copper	99+					1083 C (1982 F)
Cu-Ag alloy	50	50				778–850 C (1432–1562 F)
Easy Flo	15.5	50	16.5	18		627–734 C (1160–1173 F)
Phos-Copper	93				7	704–800 C (1300–1472 F)
Eutectic	28	72				778 C (1432 F)
ETX	34	50	16			695–775 C (1284–1427 F)

ADHESIVES AND GLUES

By Thomas D. Perry

The general terms *glues* and *adhesives* have similar definitions and are used somewhat interchangeably by most writers. Within the industry, glue more commonly refers to the older types used chiefly for wood and paper products, while the word adhesive is usually applied to the more recently developed resins and their chemical combinations for cementing together a wide variety of like or unlike materials.

PRINCIPLES OF ADHESION. While adhesion is the technique of sticking materials together, its fundamental principles have been rather inadequately investigated. It is a far more complex process than first appears. The earlier concepts represented it as a method of adhering two pieces together, chiefly by an interlocking of the prongs of the glue or adhesive, which flowed as a viscous fluid or was forced into the cavities of the surfaces to be bonded, and hardened. This is *mechanical adhesion*, and is still an important factor where porous materials are to be joined together. Later investigations developed the fact that *specific adhesion* is the more significant feature, since many relatively nonporous materials can be made to adhere in a satisfactory manner. Specific adhesion can be divided into several phases. (1) The *polarity* of the materials to be joined must be recognized, since polar solids bond readily with polar liquids, and nonpolar with nonpolar; but polar and nonpolar materials do not adhere satisfactorily. For example, water, alcohol, phenol-formaldehyde resins, and wood are polar; conventional glues (animal, vegetable, casein, soybean, and the like) have rather complicated chemical structures, but tend to be polar in character; metals, rubber, and most oils are nonpolar. (2) The *chemical* reaction of the surface of the solid to the constituents of the adhesive may indicate favorable or unfavorable combinations. (3) The pH of the glue line is important, since *high acidity* may weaken the molecular structure of the solid.

Other factors involved are the *wettability* of the surfaces to be joined with regard to the liquid glue employed; the *porosity* of the surface and its *smoothness;* the *viscosity* of the adhesive solution and the resulting *thickness* of the adhesive film; and the *evaporation* or *diffusion* of the volatile solvents.

CLASSIFICATION OF ADHESIVES. From an industrial standpoint, the volume of adhesives and glues used for *wood products* exceeds that of all other "glueable" materials. Since glued wood is frequently used for furniture, radio cabinets, and structural purposes, it is important that the adhesives produce strong and durable bonds.

Glues and pastes used for *paper* and *paper products* probably rank second in commercial importance. However, strength and durability are less essential here than in wood, since paper is relatively weak, and normal exposures are seldom exacting.

The gluing together of *metals* is a relatively new development, applying largely to thin metals where welding, brazing, or soldering are not practical. Metal-to-wood and metal-to-metal bonds are both increasing in importance.

There are numerous other adhesive applications of lesser magnitude, such as *safety glass, plastic facings* to various basic materials, *textiles, felts, leather, linoleum, ceramics,* and *rubber,* which will be briefly mentioned. Suppliers should also be consulted.

In addition to the problem of joining metal and wood, many problems are involved in uniting unlike materials such as paper and cloth to wood; plastics to wood and metal; and abrasives and granular materials to paper, cloth, and felt backings, for discussion of which the reader is referred to the literature of the industry and to adhesive manufacturers.

Primary glues and adhesives are those used for large areas, such as plywood, paper, corrugated boards, plymetal (wood to metal sheets), and plastic overlays. *Secondary glues* and adhesives are employed for assembly work, or, in the case of primary glued products, for subsequent attachment of parts. The line of demarcation is not rigid, and some of the glues and adhesives may be used for both purposes.

10. ADHESIVES FOR WOOD

FACTORS COMMON TO MOST WOOD GLUES AND ADHESIVES. Wood is a relatively porous material, with cavities that are appreciably penetrable by liquid adhesives. Hence mechanical adhesion is an important factor, supplemented by specific adhesion, as related to the physical and chemical characteristics of the adjoining solids and the intervening adhesives. Certain glues may be preferable for certain species of wood or constructions, since there is no all-purpose adhesive or glue that meets all requirements

Wettability of the wood surface by the volatile solvents in which the glue is dispersed or dissolved is an important factor. Hence all surfaces should be clean and free from oil, dust, or other impurities. Glues of high solvent ratios, such as animal and vegetable glues, require wood of extreme dryness—3 to 5% m.c., whereas those of low solvent ratios, like resin adhesives, are best made of moisture content (m.c.) ratios of 6 to 12% (in the wood), and for exposed service up to 18%. The preceding range is for room-temperature hardening. For hot press work, moisture contents should not exceed 10% for veneer layers, or be above 6% for lumber layers.

Double spreading, on both faces of a single joint, although not usually employed because of cost, often equalizes the wetting of the two surfaces that form the glue bond. *Single spreading* is customary with most of the plywood glues.

Smoothness of the wood surface is important, and fresh, sharply machined surfaces are preferable to surfaces exposed to air for periods of 2 or 3 days and up. Tooth-planed surfaces were once regarded as necessary, but this practice has fallen into disuse. Burnished surfaces, resulting from dull cutters or excessive cutting pressures, are distinctly unfavorable for gluing. Sanded surfaces may be desirable to remove gloss or polish, but are not otherwise recommended in raw wood, where sanding may cause unevenness by cutting away the softer areas. Sawed surfaces can be glued together successfully, if of accurately uniform thickness, but require higher pressures to secure close contact at the glue line.

For the best quality glue joints, all surfaces should be in *close contact*, whether flat or curved. Experience with most glues and adhesives indicates that glue line thicknesses of 0.005 to 0.010 in. give the strongest and most durable joints, although some types tolerate thicker joints.

Working life of most glues is limited, and prepared batches should come within this range, from 2 hours to a working day. Over-age batches that have passed their usefulness should be discarded. Fresh and old batches should never be combined, and receptacles should be cleaned between batches.

Various glues and adhesives *set, harden, or cure* in different ways: by (1) evaporation of the solvent, as in animal and soybean glues; by (2) polymerization or condensation, or a combination of them, under heat or catalytic action, as in resin adhesives (thermosetting); others by (3) a process of cooling, as in thermoplastics; and (4) blood albumins by coagulation. In the *thermosetting* types, heat may be required and is usually beneficial in shortening the bonding cycle. In the *thermoplastics*, heat provides a necessary flow period as an intermediate step between the application and the final curing. In glues of the solvent type moderate heat may accelerate the evaporation of the solvents, but high temperatures may weaken the bond. On the other hand, few adhesives or glues harden or cure at temperatures appreciably below 70 F, especially resin adhesives that are prepared for room temperature work. Casein is an exception, as explained under that heading.

Adequate pressure is important with most glues and adhesives, although there are a few so-called contact resins, substantially tacky in effect. Pressure should be enough to produce a thin glue line, and should be maintained uninterruptedly until the surfaces are firmly gripped together. In room temperature work, pressure should approach, but not exceed, those that will compress the wood: from 75 psi for low density woods to 125 psi for high densities. In hot pressing, since wood softens under heat, pressures that compress the wood slightly, 5 to 10%, are usually preferable; a range of 125 to 150 psi for low densities and 175 to 250 psi for high densities.

Time allowance required to obtain a firm grip between surfaces varies widely, according to temperatures and character of the glues. An overall rule might be 4 hr and up for all room temperature work, while hot press cycles may be as short as 5 min. Induction (radio frequency) heat may have as short cycles as 1 min or less, since heat is applied more directly on the glue line and is not retarded by the insulating quality of the wood to the same extent as external heat applied on the surface.

Further specific details within these general details will be found under the descriptions of the various glues and adhesives. See also references to the literature of the art, Refs. 1–13 at the end of this chapter (p. 21-30).

ANIMAL GLUES. Animal glue, the oldest known type of wood glue, was used in ancient Egypt. It approaches an all-purpose glue, but weakens rapidly when wet. It is a derivative of hide and bones, and is supplied in eighteen standard grades (see p. 21-24), varying in viscosity and jelly strength. *Hide* glue is stronger and more costly than *bone* glue. Blends are often made to meet grade specifications. Refined grades find industrial uses as gelatins; extra-refined grades become edible gelatin. *Fish* glues come under the same general classification.

The animal glue of commerce is a hard bone-like substance, tan or brown in color, supplied in flake or granular form. When soaked in cold water it swells appreciably. The swollen glue is melted with moderate stirring at temperatures up to 140 F, and is kept at approximately that temperature while in use. Since animal glue tends to harden when chilled, wood is often warmed slightly before application. Both brush and roller application are used. Average clamping time is 4 hr, although some low water ratios can be unclamped in 2 hr, both at room temperature. Heat should not be used to shorten the setting time.

Utility Range. Animal glue is widely used for assembly work, as its cost bars it from most plywood work, except occasional special pieces. As a bench glue for general purposes it is unsurpassed. Many traditional cabinet makers prefer it to all other glues. As a dilute size, or as an ingredient in various combinations, it may be used to fill the pores of the wood and increase their cohesion, as in strengthening fragile face veneers.

Durability. Animal glue joints, when not exposed to moisture, have retained their strength for many years, even for centuries. Animal glue is not suited to products exposed to the weather, to boat work, to high humidities, or to high temperatures. Properly made animal glue joints not unduly exposed are stronger than the wood itself.

BLOOD ALBUMIN GLUES. These glues, more correctly designated as *dried-blood glues*, are divided into *soluble* and *insoluble* types. Soluble grades were used for aircraft in World War I, before resin adhesives were available, when few hot presses had been installed.

Commercial dried blood of the soluble type is supplied in powder form and is dissolved in water, usually with some toxic ingredients to inhibit mold and fungus growths. Insoluble types require the addition of caustic soda and other chemicals to convert them to adhesive uses. Roller spreading is employed for plywood work, single spread on either of the two mating surfaces. If roller spreaders are not available, brushes may be used. Blood glues harden by the coagulation of the albumin, at hot press temperatures of 120 to 180 F. Except with special formulas, seldom used, blood glues do not set at room temperatures. The irreversibility of the coagulation process, under heat, marked an early step in waterproof plywood.

Utility Range. While soluble blood glues were used for hot-pressed plywood with minor additional ingredients from 1910 to 1925, they were gradually displaced by casein and resin adhesives, which were more uniform in grade and more reliable to use. Albumin glues are not suitable for assembly or bench work. Both soluble and insoluble types of blood glue are currently used largely as modifying and extending agents in resin adhesives. In such combinations the blood additives regulate the spread and flow and shorten the hot press cycles, as well as reduce the average cost of the adhesives.

Durability. Plywood made with straight blood glues has excellent durability under severe exposure, but deteriorates slowly in storage, and is adversely affected by mold, fungus, and insect pests, except where proper inhibiting reagents have been added. Bonds in which blood is combined with other adhesives partake largely of the durability of the other adhesives. Blood and resin combinations are used in Douglas fir plywood on the Pacific coast, but do not meet the exacting requirements of standard exterior grades.

CASEIN GLUES. Primitive glues of this type, made of sour milk and quick lime, date back several hundred years, but modern commercial adhesive uses began in the early 1900's. Casein is the dry powder from curds of milk, natural- or acid-soured, and an important by-product of the dairy industry. After the removal of whey, the curds (crude casein) are washed, pressed dry, and the cake is broken and ground into a powder of the proper degree of fineness. Raw caseins vary widely in quality, and suitable adhesive types must be selected and segregated.

Preparation. Casein glues for woodwork consist chiefly of a suitable grade of casein, hydrated lime up to 15% (of casein) and caustic soda with other minor ingredients including, sometimes, certain chemical preservatives. Prepared powder combinations are usually employed, although the caustic may be added at the time of mixing. Casein for plywood work is applied by corrugated (12 per in.) metal rollers. For assembly and bench work, brush spreading is employed.

Clamping requirements for plywood at room temperatures are 4 hr and up, although most factory practice is to allow the plywood to remain overnight in clamps. This hardening is both by evaporation and by the chemical formation of calcium caseinate. It is an irreversible process of the order of concrete. Setting may be accelerated by heat. In field operations in housing, casein cures at temperatures of 50 F, but at a retarded rate.

Utility Range. Casein glues are used for water-resistant plywood as well as for assembly work. When hardened, casein joints have a somewhat abrasive effect on tools. Casein is used only to a limited extent in furniture and interior equipment because of cost. It is used extensively in laminated timbers and has many structural applications where exposure is not extreme. Casein is frequently combined with dried soluble blood, soybean, and silicate of soda glues, and is a useful component in such combinations.

Durability. Plywood made with the better grades of casein is highly water resistant and finds many fields of utilization where extreme durability is not required. It has excellent resistance to heat, below that which chars wood, but delaminates on prolonged soaking or exposure to high humidities. It is considerably below urea resins in water resistance, and superior to ureas in heat resistance.

SILICATE OF SODA GLUES. Soluble silicates are made by melting sand and soda ash in an open hearth regenerative furnace at temperatures of 1300 to 1500 C. The melt is leached of water-soluble constituents. The grades used for wood adhesives are:

Soda-silicate ratio, 1 : 3.22; Baumé rating, 41° to 42°; solid form
Soda-silicate ratio, 1 : 2.9; Baumé rating 47°; liquid form

The former is preferable for open porous woods, the latter for hardwood plywood.

Most formulas provide for combinations of silicate of soda with lime and casein, to reduce the overall cost of casein. Formulas are somewhat complex and suppliers should be consulted. Spreading is by corrugated (10 per in.) metal rollers, single spread. The hardening action is by solvent evaporation, and the joint has a slightly abrasive action on edge tools. Heat is not employed to accelerate the setting.

Utility Range. Silicate of soda glues have been extensively used for plywood box shooks, but their use has substantially declined because of their somewhat complicated formulation. This type of glue finds wider use in corrugated fiber and paper packages. It is also an important low-cost extender for other glues, such as soybean glue.

Durability. Bonds made with silicate of soda are reasonably strong, are adequate for box shooks, are highly resistant to mold and fungus growths, but have low water resistance.

SOYBEAN GLUES. Soybean is a relatively new adhesive for plywood, developed on the Pacific coast just prior to 1930, especially for the Douglas fir industry. The oil is first pressed out of the soybeans, and the resulting cake or meal, or such part of it as has desirable adhesive qualities, is dried and ground to a powder. Peanut meal flour, similarly extracted, is also used as an adhesive but is not as highly regarded.

For room temperature work single spreading is employed, corrugated (10 per in.) metal rollers being used. For hot pressing, rubber rollers, with 16 to 20 corrugations per inch, are used. Soybean glues will harden at room temperatures in 4 hr and up; by one-stage hot pressing requiring 4 $^1/_2$ min for $^1/_2$ in. 5-ply, when platens are at approximately 225 F; or by a two-stage process under the same conditions in 2 $^1/_2$ min.

Utility Range. Soybean glues are widely used for Douglas fir plywood and with associated species. They are also used to a considerable extent for hardwood plywood box shooks. They are seldom used for furniture, except for drawer bottoms, dust backs, etc. Soybean glues are low in cost, but their high alkalinity is somewhat of a handicap.

Durability. Soybean glues produce bonds of substantial moisture resistance, for all grades of Douglas fir except exterior and concrete form types.

SYNTHETIC-RESIN ADHESIVES. PHENOL FORMALDEHYDE. Synthetic-resin adhesives began to attract attention in the early 1930's. The earliest commercial type was made from phenol, a coal tar derivative, combined with formaldehyde, partly condensed or polymerized by the supplier and sold to the consumer as a thermosetting adhesive for wood. Cresol was sometimes used instead of phenol. The polymerization is completed in contact with the wood, under heat and pressure, resulting in a bond of maximum durability.

Types. The best-known phenol type is Tego film, which is supplied on a paper carrier ready to use, furnishing a uniform and adequate amount of adhesive per joint. Its principal use is in hardwood plywood. Phenolic adhesives are also available in liquid and powder form, which in the latter form require preparation by the user. Liquid phenolics, 40% solids, are widely used for Douglas fir plywood. Most phenolics cure at platen temperatures of 275 to 325 F, but modified phenolics cure at temperatures of 150 to 200 F.

Durability. Phenolic-resin adhesives are used chiefly for exterior and marine grades of plywood, both hardwood and softwood, but are not used for assembly work. Exposure tests of many years' duration have demonstrated that a properly cured phenolic bond is more durable than the wood itself.

Impregnation with Phenolic Resins. Phenol-formaldehyde resins, less advanced than those used for adhesives, are found suitable for impregnation, the preliminary step to making Compreg, Pregwood, etc., under high pressures. Such resins, of small molecular size, penetrate into the minute cavities of the cell walls of the wood. Thorough impregnation requires veneers of $^1/_8$ in. and thinner. The impregnating treatment may be by soaking for 1 to 2 days, by several vacuum-pressure cycles, or by pressure cycles alone; the last two methods require 2 to 3 hr for a resin pick-up of 25 to 30%. Pick-up is the percentage of dry cured resin impregnant by weight, based on the raw dry wood as 100%.

Pressures required for Compreg are 1500 to 3000 psi, with a resulting specific gravity of 1.3 to 1.4. Hardwoods, like maple and birch, are compressed under this process to approximately two-thirds of their original thickness. Less dense species such as poplar may be compressed to one-half the original thickness. Impreg is similarly impregnated with resin, but cured at lower pressures, 200 to 300 psi.

Other impregnating processes include Tegowood, made by similarly curing Tego interlayers between veneers approximately 1/30 in. and thinner. Another process is by double-spreading a liquid phenolic on veneers 1/16 in. thick, followed by the cure cycle outlined above.

SYNTHETIC-RESIN ADHESIVES. UREA FORMALDEHYDE. Urea-resin adhesives are a later development than the phenolics, appearing in the late 1930's. Urea is a synthetic product, based on a reaction between carbon dioxide and ammonia. When combined with formaldehyde, its thermosetting adhesive characteristics resemble those of the phenolics, but with shorter curing cycles, lower temperature requirements, and reduced ultimate durability. Urea-resin adhesives have a wide range of versatility, and when properly cured exhibit durability considerably higher than the earlier conventional glues.

Urea-resin adhesives are available in powder and liquid form, are soluble in water, may be catalyzed for room temperature cure at 70 F, or hot pressed at 225 to 275 F, may be extended with wheat flour in varying ratios, and may be fortified by additional ingredients to produce bonds approaching those of the phenolics for durability. Single spreading may be by grooved (16-20 per in.) rubber rollers, brush, or spray. Plywood bonds in panels 1/4 in. thick can be cured in 6 to 7 min with hot press platens at 250 F. This time in the hot press can be shortened by completing the bond under residual heat in a subsequent hot stack for 4 hr immediately following removal from the hot press. Assembly bonds are usually cured at room temperatures of 70 F and up, with 4 to 6 hr and up under full clamp pressure. Properly catalyzed urea adhesives are extensively used under electronic heating. Each manufacturer should be consulted for bonding schedules on his resin adhesives.

Durability. Ureas are by far the most-used resin adhesive, with excellent records of durability under normal protected exposures. Extreme moisture or exposure to heat above 150 F is distinctly unfavorable, and phenolics should be employed.

OTHER SYNTHETIC-RESIN ADHESIVES. Resorcinol formaldehyde is a phenolic type in liquid form, requiring a separate catalyst. Cures are at room temperatures of 75 F and up. Durability of bonds for marine and weather exposure is improved by curing bonds at 180 to 220 F, in heated chambers with high humidity to prevent wood shrinkage and pressure losses. Resorcinols are especially adapted to laminated lumber and assembly joints subject to severe exposures. For massive and bulky assemblies where heat applications are difficult and slow, resorcinols give bonds equal to standard phenolics in durability. Resorcinols are in high cost ranges and hence impractical for plywood work.

Melamine formaldehyde is a urea type, for hot pressing only, with better durability than the standard ureas, but in higher cost brackets. When properly applied, melamines approach the durability of the phenolics and resorcinols. Their background of development and their experience in durability tests are both quite limited in comparison with the ureas and phenolics.

Thermoplastic Resin Adhesives. Polyvinyl resins of several types have distinct adhesive qualities and have had a number of successful applications in wood and like products. Because they were developed no longer ago than 1946 they should be used cautiously.

VEGETABLE GLUES have a starch base, and wood glues consist principally of cassava or tapioca flour, made from the fibers of the cassava roots and imported from the East Indies. Corn and potato starches are also used, especially for low-grade plywood, as in box shooks. Vegetable glues appeared about 1910, and were widely used for plywood until the advent of extended urea-resin adhesives about 1940.

Utility Range. When low cost is important and water resistance is not a factor, vegetable glue may be used. It has been generally employed in medium- and low-grade furniture. Its use declined severely during 1940–1945, when imports of cassava were drastically curtailed, and it is not clear whether it will regain its former importance as a wood adhesive.

Durability. While vegetable glue bonds have a long life when protected from moisture, they are distinctly deteriorated by high humidity and moisture. They can be recommended only for locations well protected from adverse conditions.

GLUE TESTING. Animal glue standards adopted by the National Association of Glue Manufacturers are not applicable to any other glue or adhesive. The eighteen standard grades are based on jelly strength and viscosity. Grades 9 to 12 are recommended for high-grade joint glues in woodworking. A wider range may be used for less exacting wood joints, i.e., 7 to 15. Little hide glue is found in grades below 7; lower grades are usually blends of bone and hide glue, and the lowest grades are chiefly bone glue.

Jelly strength test is the weight in grams required to embed a plunger 12.7 mm in diameter to a depth of 4 mm in a standard mixture. *Viscosity* is a measure of the time in seconds required for a solution to flow between two points on a capillary-type pipette that has been properly calibrated in millipoises.

TESTING GLUE JOINTS. The testing of glue itself is limited to grades of animal glue, since there are so many variables in other glues and adhesives, due to heat and chemical reactions, that no practical standards have been found that are reasonably reproducible under normal conditions. However, standards of glue joint strength applicable to most glues and adhesives have been developed by the Forest Products Laboratory and have an adequate background of experience for evaluating glue joint strength under normal and exposure conditions. These tests show *tensile shear* strength in plywood (Fig. 1) and *compression shear* strength in solid wood blocks (Fig. 2).

Tensile Shear Strength in Plywood. Sample test strips of $^3/_{16}$-in. birch plywood, 1 in. wide by 3 $^1/_4$ in. long (Fig. 1), with single saw slots on opposite sides extending two-thirds through the central cross layer, are cut from selected or random locations in the plywood sheet. These samples are tested to destruction, usually breaking in the central cross layer. Thus the test is *across* the grain of the central layer.

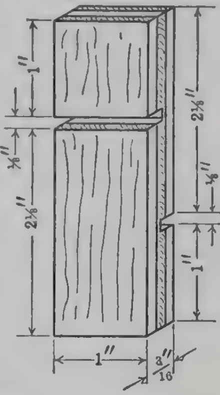

FIG. 1. Test specimen for tensile shear strength of glue joint in plywood.

Birch is a sufficiently strong species to give an adequate demonstration of adhesive strength, and the usual requirements for breaking tests are approximately 400 psi *dry* and 300 psi *wet*, after cycles of wet and dry exposure. In less dense woods the requirements are approximately 230 psi *dry*, and 130 psi *wet*. Reference is made to specifications AN-G-8 (1942) and AN-P-69a (1947) for further details as to government requirements for dry and alternate cycle tests of this type. The commercial requirements are given in CS-35-47 and CS-45-47. Because revisions are frequent, the latest editions should be obtained from the Bureau of Standards.

Compression Shear Strength in Solid Wood Blocks. Sample test blocks are glued together, sawed apart into specimens 2 in. wide by 2 in. long by approximately 1 $^1/_2$ in. thick, stepped down to give a test area of 3 sq in. *along* the grain, as shown in Fig. 2. Maple is chosen as standard, being a wood difficult to glue and of adequate strength for comparative purposes. Single test specimens can be made of strips of dense maple, glued together and cut apart as shown in Fig. 2, or they can be cut from multilaminated pieces.

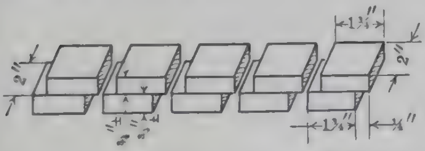

FIG. 2. Test specimen for compression shear strength of glue joints in solid wood blocks.

The requirement for dense hard maple is 2800 psi, for white oak 1800 psi, and for Douglas fir and other less dense species lower strengths. Cyclic wet and dry tests are employed for joints to be subject to marine and weather exposure.

Reference is made to specification AN-G-8 (1942) and JAN-A-397 (1946) for further details of government requirements for dry and cycle tests of this type. No commercial requirements have been established.

11. GLUES AND ADHESIVES FOR PAPER PRODUCTS

Such adhesives function largely on porous materials such as paper and fiber boards. Included also, for lack of a more logical classification, are a few relatively nonpenetrable materials, such as transparent adhesive tapes and packaging closures of the cellulose types. Paper-reinforced metallic foils are of a similar character. The ramifications of these adhesive problems and the range of combinations of basic adhesive materials and supplementary ingredients are very great. The most practical approach, for a brief survey, is to describe the groups of materials to be adhered and to indicate the adhesives that have proved generally useful. For further information the reader is referred to adhesive suppliers.

LAMINATED PAPER AND TEXTILES. Many types of standard papers are combined, somewhat as in plywood, to provide attractive or printable surfaces on center or backing layers of strong and relatively thick fiber boards of low cost. For such laminated products, adhesives are chiefly of raw starch and partially (20 to 30%) dextrinized starch. While cassava starch (tapioca) is noted for the cohesiveness of its paste, corn and potato starches are widely used.

Silicate of soda may be combined with the starches, either to reduce the time of gelatinization or to decrease cost. Neither starch nor sodium silicate glues have appreciable water resistance, but this is seldom important in laminated papers.

Cloth may be combined with paper as a reinforcing layer, the above glue combinations being used, but the relative shrinkage ratios of the materials need careful consideration.

CORRUGATED AND SOLID LAMINATED FIBER BOARDS. The adhesive problems in this field are akin to those of paper, but the glues must be in minimum cost ranges. Two types of adhesives, starch and silicate of soda, are widely used. The starches are of the corn or tapioca types, whichever is cheapest at the time, and are modified to meet particular types of fiber board. Starches combined with urea-resin adhesives substantially improve the water resistance of the bond. Silicate of soda is widely used, since a rapid development of tackiness is essential and the required moisture resistance is seldom important.

WATER-REMOISTENABLE APPLICATIONS. Adhesives for gummed labels, envelopes, postage stamps, etc., are known as water-remoistenable types, since they must be applied, dried, and stored in reasonable locations, without causing premature adhesion. When moistened with water or saliva, they must develop prompt tack and adhere with finger pressure. Moisture resistance, after they are stuck together, is seldom an important factor.

Unconverted starch gives the best bonding qualities, but exhibits the poorest remoistening characteristics. Partially converted dextrine (50 to 75%) is more soluble but gives hygroscopic bonds. Animal glues and dextrines are used in various combinations to impart greater strength and to reduce crystallization.

For postage stamps either dextrine or gum arabic is employed, and curling is retarded by passing the dry gummed sheets between metal rollers that tend to break the glue film by slight corrugations. Gummed labels to adhere to glass bottles and paper surfaces present special problems of adhesion. Animal glues are frequently added to the dextrines. Decalcomania labels are usually coated with animal glue or glycerol.

GUMMED AND ADHESIVE TAPES. Tapes fall into two general types: (1) those that are *gummed* and *remoistenable*, as in the case of gummed labels; and (2) *adhesive* tapes that do not require remoistening. Gummed tapes for splicing veneers usually employ modified animal glues; but for package closures, the starches, dextrines, and animal glues are used. Nonblocking to the ungummed face is important for storage purposes, and surface sizings are frequently used. Gummed tapes may be made of cloth or perforated paper, the latter being employed for inner layers of veneer in plywood constructions.

The other principal type is the so-called *adhesive* tape, which is pressure sensitive and requires no moistening during application. A considerable number of chemical combinations have been developed for this purpose, many of which have rather complicated formulas. Most of them contain substantial proportions of various types of rubber and of a number of resin adhesives.

Masking types of tapes, for spray lacquering, are usually on crepe paper with a protective coating on the nonadhesive side. Such masking tapes do not require particular strength but, when removed, must leave no deposit or residue for the application of another color of lacquer.

Adhesive tapes for sealing packages are made with a crepe paper or cloth backing, requiring strong and durable adhesives on a substantial background. Their removability is unimportant.

BOOKBINDING ADHESIVES. Bookbinders customarily use two types of glue, one for the flexible parts, and another for the rigid parts, such as "board" covers. Selected and modified grades of animal glue have long been used for the back and flexible covers, both of which are continually subject to bending stresses. Certain types of resin adhesives are coming into wider use because of the shorter setting cycles, better flexibility under aging, and less susceptibility to moisture.

Starch pastes are usually used for "casing-in" or attaching the book to the cover, since these pastes are in the low-cost ranges and flexibility is not a requirement.

ABRASIVE MATERIALS. Adhesives perform an important function in sandpaper, emery cloth, and other sheeted abrasives. Formerly high grades of animal glue were employed. With the demand for better moisture resistance, as in wet rubbing, and for heat resistance, as under heavy cutting feeds, phenol-formaldehyde resin adhesives have come into use. These are thermosetting and have greatly increased the all-round durability of abrasive papers and cloths.

LIQUID ADHESIVES. For package closures, starch adhesives are prepared in liquid form with a wide range of ingredients for innumerable applications. Silicate of soda is also used, but its preparation is more complicated. Suppliers should be consulted for further details.

12. ADHESIVES FOR METALS AND DENSE MATERIALS

PROBLEMS OF METAL ADHESION. In the cementing together of metal, specific adhesion becomes important, since the penetration of adhesives into the surface is insignificant. Adhesives for metals were developed recently, under the urge of military necessity. It appears quite certain that their importance will increase as they are better understood and evaluated.

Surface Preparation. An important phase of any metal-to-metal gluing is the proper and adequate degreasing of the metal surfaces to give the adhesives a strong "bite." The surfaces of the metal should be cleansed thoroughly of any oil, grease, or other foreign materials. This may be done by the solvent wipe, vapor degrease, or by immersion in a heated acid bath, all as explained in British specification D.T.D. 915. After such treatment, the metal surfaces should be washed and dried. An alternate method is abrasion by steel wool, sandpaper, emery paper, or sandblasting, after which the surfaces should be washed, wiped, and dried to remove all dust particles.

A slightly roughened, rather than a smooth or polished, metal surface is desirable for strong durable joints. A simple test for adequately cleaned metal surfaces is to flow water over them, where it should form a continuous and unbroken film.

It is important that there be no unnecessary delay between cleaning the surfaces of the metal and applying the adhesive. Intervals of one to three hours may not be serious, but overnight delays may reduce the quality of the bond. After a week or ten days surfaces should be recleaned before bonding.

Design Requirements. Metal-to-metal joints, in lapped constructions, have attracted especial attention, since riveting has distinct limitations in thin lightweight metals, and welding, spot or seam, presents other types of difficulties, such as metallurgical changes in alloys at welding temperatures.

Any lap joint in tensile shear tends to distort, as shown in Fig. 3, thus combining a major factor of true shear along the joint with a minor effect of true tension across the joint. The extent of distortion, or eccentricity, is materially influenced by the thickness of the metal and the length of the overlap. The simplest form of lap is the plain, or square-end, overlap as shown in Fig. 3. It might be expected that a lap 1 in. long would be twice as strong in shear, as a lap $^1/_2$ in. long, but such is not the case. The disturbing influence is the elasticity of the metal, together with the distortion noted above, which causes greater stresses at the extremities of the lap than at its center. If the overlap is beveled down, the relation between the 1 in. and $^1/_2$ in. laps is greatly improved. A comparison of such lap constructions is shown in Fig. 4, where the "expectation" of normal strength increase is a straight line at the left of the chart, while the actual shear strength of plain lap joints is shown in the lower line, which approaches the horizontal. The shear strength of the beveled lap joint falls between the two lines, and does not diverge greatly from the expectation line. However, such beveled joints are likely to present difficult production problems and their strength, while recognized, has not been evaluated to any important extent.

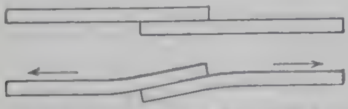

FIG. 3. Distortion of a lap joint in shear.

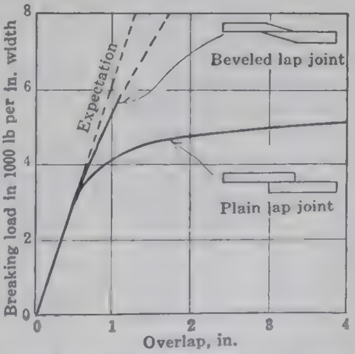

FIG. 4. Strengths of plain and beveled lap joints.

Studies have been made by Dr. N. A. de Bruyne of Aero Research, Limited (Ref. 14), on plain lap joints cemented together by Redux which are believed to be typical of other metal-to-metal adhesives of comparable strength. This research work has determined that the strength of the metal-to-metal lap joint varies directly as the width, while the effect of the metal thickness and overlap is expressed by the equation:

$$\text{Joint stress factor} = \frac{\sqrt{\text{Metal thickness}}}{\text{Overlap of joint}} \text{ (expressed in inches)}$$

A nomograph was developed expressing these relations, and from this nomograph, Figs. 5 and 6 have been derived. These curves apply to duralumin and steel.

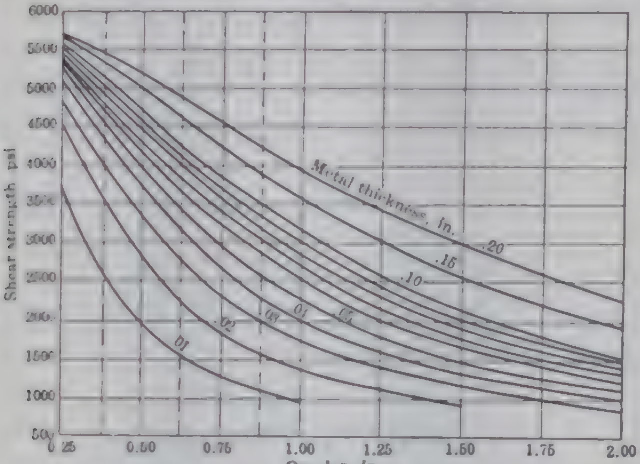

Fig. 5. Ultimate shear strength, psi, of metal-to-metal Redux lap joints.

It is to be noted (Fig. 5) that, although the maximum shear strength may be between 5000 and 6000 psi, the actual obtainable unit shear strength on most constructions is distinctly less, with definite decreases as the joints become longer and increases as the metal becomes thicker. The data given in these curves are in *pounds per square inch* of actual contact area. If the anticipated loading and metal thickness are known, the required overlap can be read from the chart.

The data given in Fig. 5 have been converted into the total strength of lap joints 1 in. wide, and have been recharted in Fig. 6. These curves indicate the length of overlap for a given metal thickness that will produce *maximum joint strength per inch of width*. Thus with two known variables, among three, the third can be determined from Figs. 5 and 6. These fundamentals of attainable strength are important in design problems.

Exhaustive tests by the U. S. Navy have shown that a combination of rivets and Redux adhesives gives several times the tensile strength of rivets alone. The economic phases of such a combination joint may be somewhat of a problem in commercial applications, but the ultimate strength of the joints is well demonstrated.

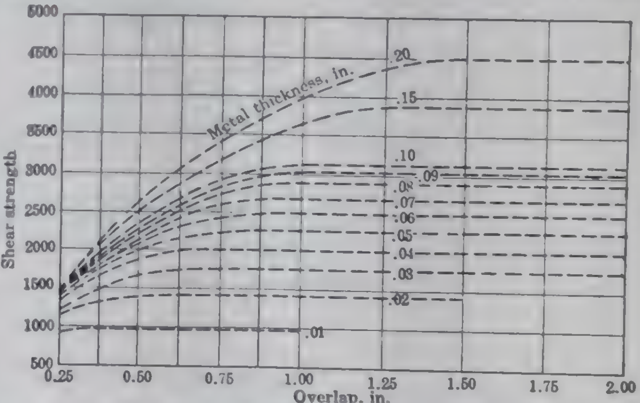

Fig. 6. Ultimate shear strength of metal-to-metal Redux lap joints one inch wide and of indicated overlap.

CLASSIFICATION. A number of metal-to-metal adhesives have been developed but their use has been confined largely to lap joints or spot joints of relatively limited area. Laminated all-metal sheets have not yet become commercially important. Metal-to-wood adhesives, as employed in making plymetal, have industrial applications of appreciable volume, and are discussed in this article. Among the metal-to-metal adhesives, the following have attained recognition:

Redux, Rohm and Haas Co., Resinous Products Division, Philadelphia, Pa.
Cycleweld, Chrysler Corporation, Detroit, Mich.
Plastilock, B. F. Goodrich Chemical Company, Akron, Ohio.
Reanite, U. S. Stoneware Company, Akron, Ohio.
Metlbond, Consolidated Vultee Aircraft Corporation, San Diego, Calif.
Araldit, Ciba Products Corporation, Kimberton, Pa.
Robertson Bonded Metal, H. H. Robertson Company, Ambridge, Pa.

The processing requirements for the first two are outlined, briefly, herein. For further details on these, and for data on the others, the literature of the suppliers should be consulted.

METAL-TO-METAL ADHESIVES—REDUX. This is a two-component adhesive, used successively and not combined, a brownish liquid (phenolic) and a white granular powder, developed originally in England. It is chiefly thermosetting, with some thermoplastic characteristics, and cannot be catalyzed for room temperature work. The liquid should be stored in tight receptacles at approximately 40 F. If separation occurs before use, it can often be redispersed by stirring. If a smooth mixture is not obtainable, the material should be discarded. When properly applied and cured, it produces lap joints with tensile strengths exceeding 5000 psi on joints of favorable design. Tensile shear tests are made for evaluation, as shown in Fig. 1.

Application. Metal surfaces should be properly cleansed, as previously mentioned. As soon as practicable after cleaning, the liquid should be brush-applied on the joint area, at the rate of 20 to 25 lb per 1000 sq ft per surface, or 40 to 50 lb per joint. As much powder as will stick is immediately dusted on the liquid, and any surplus is tapped off. Solvent evaporation should follow, from 1 to 24 hr at room temperature, sometimes longer. Forced drying at 125 to 150 F may be used to accelerate this drying. The pieces are assembled, taped to prevent slippage, and cured between metal platens heated to 275 to 325 F, at pressures of 300 to 500 psi for approximately 15 min. Pressures should be adequate to reduce glue-line thickness to 0.003 in. to 0.006 in. Under favorable conditions, with close-fitting surfaces, pressures may be as low as 100 psi. Pressure may be released, usually, while assemblies are hot, except in the case of unlike metals, in which rates of heat expansion vary significantly.

Metal Types to Be Bonded. Most Redux tests have been made on aluminum alloys, but satisfactory results also have been obtained on stainless steel, magnesium alloys, cold-rolled steel, and galvanized steel. Results with nickel and its alloys have not been satisfactory. Lead and copper, with their derivatives, do not bond well. Joints of significant area between metals of unlike rates of heat expansion are seldom satisfactory. An example of this would be a cast-aluminum handle against a steel blade in a plasterer's trowel.

Durability. Redux bonds in aluminum have excellent durability under room temperatures and at low temperatures down to −125 F. At elevated temperatures of 175 F, Redux joints may exhibit 60 to 75% of normal strength, but weakening progresses significantly above that point. Continuous exposures to salt-water spray for 10 days show little loss of strength. Strengths are well maintained on exposure to liquid fuels (45% aromatic), engine oil, and hydraulic fluids, such as oils, glycol, and water.

METAL-TO-METAL ADHESIVES—CYCLEWELD. Cycleweld cements come in several types for different purposes, so that suggestions as to applications must be in general terms, and further details should be obtained from the suppliers. Most types of this adhesive are supplied as dark-colored liquids of limited stability, containing a base of natural or synthetic rubber. In general those that gel in storage can be reconditioned by heat and stirring. When properly applied and cured, they produce lap joints with tensile shear strengths of 4000 psi where designs are favorable for maximum strength.

Application. Metal surfaces should be properly cleansed, as previously mentioned. As soon as practicable after cleaning, the liquid should be applied, preferably by spray gun, but sometimes by brushing or roller coating, usually with 3 to 5 coats on each surface of the joint, with intervening flash periods of 5 to 10 min between coatings. These combined applications, after drying 15 to 48 hr at room temperatures, or accelerated in an oven at 180 F or less, are ready for assembly and should be taped in position to prevent slippage. Hot-press curing is at temperatures of approximately 325 F, for 15 to 20 min, at pressures of 200 psi. Some types can be cured at lower temperatures, as can well-fitted joints at lower pressures.

Metal Types to Be Bonded. Most Cycleweld tests have been made on aluminum and its alloys, but different types of this adhesive are available for most of the common metals, as well as for cast, molded, and laminated plastics and rubbers. Special types are available for materials that deteriorate under normal temperature and pressure requirements. Joints of significant area between materials of different expansion factors require special consideration.

Durability. Cycleweld bonds exhibit excellent durability at normal room temperatures for extended periods, as well as at low temperatures down to −70 F. At elevated temperatures some types withstand 300 F, others 150 F, and suppliers should be consulted. Oil resistance is excellent, but in general salt spray has a deteriorating effect unless the joint is adequately protected. With diverse nonmetallic materials, durability to exposure is usually that of the nonmetallic material.

METAL-TO-WOOD ADHESIVES. Plymetal is a combined wood-metal product, in which metal sheets are used with wood layers, either for facings or interlayers, adding greatly to stiffness, strength, and surface hardness. Since the expansion, under heat, between metal and wood creates undue stresses, most metal-to-wood bonding is done with room temperature adhesives. Exceptions are facings of very thin metals, almost in the foil range, where the expansive force of the metal is not dominant.

Casein latex glues have been used for many years in plymetal constructions with excellent results. Such joints have good strength properties and satisfactory durability under moderate exposures, but are not suitable for marine or extreme weather exposure. The application procedure follows closely that of the wood ahesives, except that the metal facing is usually a separate bonding operation after the plywood has been dimensioned to size and planed or sanded to accurate thickness. Metal surfaces, usually aluminum or steel, must be thoroughly cleansed from oil, grease, etc., before gluing. Interlayers may be assembled in single or double gluing steps.

Coated Metal Sheets. A more recent development is the sizing, priming, or precoating of the metal sheets with Redux, Cycleweld, or other metal adhesive, which is cured in situ by oven or platen heat, against a nonadhering caul. Such precoatings must be thin, not over 0.007 in., and of uniform application without lumps or irregularities. A second gluing operation is one that combines these precoated sheets with layers of veneer or wood, utilizing room temperature resin adhesives of compatible types, under usual plywood pressures with required clamping cycles. This method avoids undue stresses in the gluing process.

A unique development in this class is Robertson bonded metal, a process which solders a textile fabric to a thin metal sheet with a low-temperature solder, quenched quickly to avoid burning the fabric seriously. Layers of veneer can be glued normally to the cloth side.

Wood-to-metal Assembly Joints. Assembly joints of any wood-to-metal area can be made by the foregoing precoating process. Where assembly joints are of limited area, and can be adequately heated, a metal adhesive can be employed on the metal side, with a compatible wood adhesive on the wood side, to be cured simultaneously by heat. This process has been used in constructing wood-metal aircraft in England.

13. ADHESIVES FOR RUBBER, GLASS, LEATHER, ETC.

Adhesives have been developed for a wide range of materials other than those described for wood, paper, and metal.

RUBBER. Many rubber cements have been developed from natural and synthetic rubber ingredients and latices. Blood albumin, casein, and the phenols are some of the additional ingredients. Other chemical derivatives have been used, butadiene being an outstanding example. All the larger rubber companies have been active in this field; their literature should be consulted for further details.

GLASS. The adhesives used for optical purposes are usually Canadian balsam. Several of the polyester resins have given satisfactory results and are approved for certain types of lenses and prisms. Sheets of safety glass are usually glued together with polyvinyl butyral resins, but a number of other similar adhesive resins have also been used successfully. The suppliers should be consulted.

LEATHER. Animal glues have long been popular in this field, as have other chemical compounds, most of which are tacky and set quickly at room temperatures. Electronic heat with resin adhesives is used in some cases for short progressive bonding cycles. Many types of latex are used alone, or in combinations, since flexibility is an important consideration in leather products. The literature of the industry should be consulted. There are many other adhesive applications in diverse fields for which data can be obtained in Ref. 12.

INDUSTRIAL FURNACES

By W. Trinks

The purpose of industrial furnaces is to heat solid, processed material so that the product, after cooling, has no flaws or defects which can be attributed to incorrect heating. In general, *ovens* heat material to less than 1000 F, and furnaces heat material to more than 1000 F. In *kilns*, water or carbon dioxide is first driven off the charge, which is then heated further. Materials to be heated are, as a rule, metals, but ceramic materials are also heated in industrial furnaces and plastics are heated in ovens.

The temperatures to which iron and steel are heated for various operations are given in Table 1. For other metals, temperatures are kept well below the melting points. For the latter values, see p. 1-04, or Fig. 1.

Table 1. Furnace Temperature Range for Industrial Processes on Iron or Steel

Process	Temperature Range, °F	Process	Temperature Range, °F
Hammer or press welding	2350 to 2550	Hardening carbon steel (quenching)	1450 to 1550
Hardening high speed steel *	2200 to 2400	Annealing cold-rolled steel	1250 to 1400
Drop forging	2250 to 2370	Drawing	1150 to 1200
Rolling (low-carbon steel)	2150 to 2275	Nitriding	950
Bending and rough forming	1900 to 2100	Tempering	500 to 800
Normalizing, also for carburizing	1650 to 1750	Bluing †	500 to 650
Rough annealing	1500 to 1650		

* Special steels require various temperatures for hardening, usually ranging from 2400 F for greatest hardness to 1850 F for greatest toughness (for tungsten steel).

† Temperatures for drying and japanning are still lower.

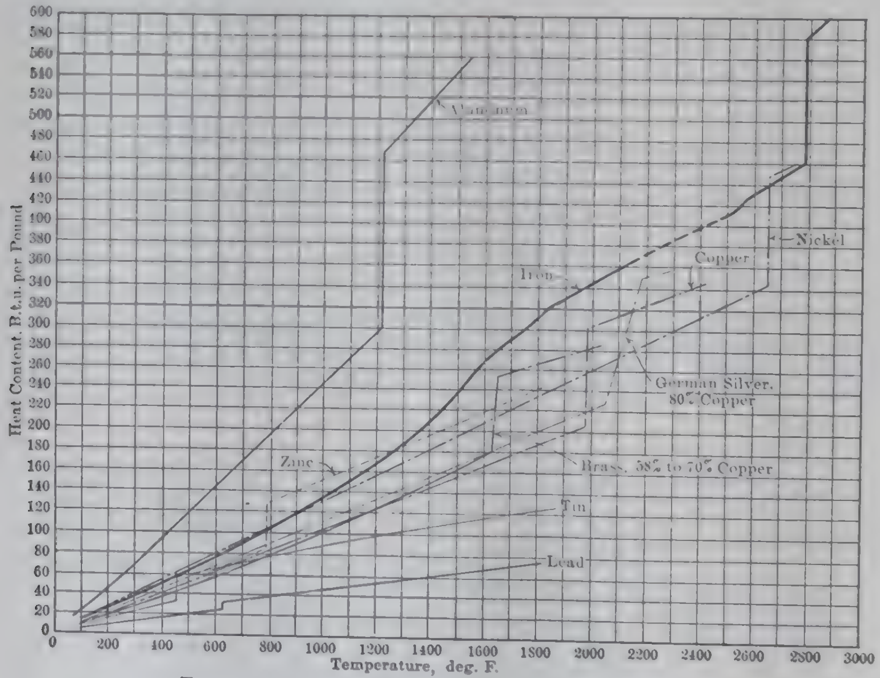

Fig. 1. Heat content of metals at various temperatures.

Design and construction of industrial furnaces have reached a high degree of perfection in the United States. It pays to install a furnace that was designed and built by a reputable furnace builder.

1. FURNACE CHARACTERISTICS

CLASSIFICATION OF FURNACES. Furnaces are classified:

According to use, such as reheating, forge, annealing, bright-annealing, heat-treating, and normalizing furnaces; and soaking pits.

According to the material or shape which they heat, as rivet, bolt-heading, plate, and angle furnaces; and brick kilns.

According to the movement of the charge in the furnace, as batch (also called in-and-out type), continuous-pusher, automatic or continuous conveyor, rocker-bar or intermittent-conveyor, and car type furnaces; and furnaces with a rotating hearth or with revolving drum.

According to the fuel or other source of heat energy, as combustion, gas-fired, oil-fired, electric-resistor, and induction furnaces.

According to the method of fuel saving, as regenerative, recuperative, and preheating-chamber types.

In muffle furnaces the charge is heated in a gastight enclosure and is separated by it from the source of heat. Pot furnaces are muffle furnaces.

ECONOMY OF HEATING must be based on unit weight of perfect product. The term "perfect product" involves such features as freedom from internal cracks caused by too rapid heating, uniformly high quality of heat-treated products, uniform annealing, uniform enamel of first quality, proper distribution of hardness, freedom from scale and ashes, freedom from burning of high-carbon steels, etc. In certain operations, such as plate bending, railroad spike forming, bolt heating, and tool hardening, uniformity of temperature throughout the heated stock is not necessary.

True heating economy is inversely proportional to total cost per unit of product. It can be expressed by

$$E = W \div (I + M + L + F)$$

where E = true heating economy; I = interest on investment; M = cost of maintenance; L = cost of labor, including overhead; F = cost of fuel; and W = unit weight of perfect product.

The amount of capital that profitably can be invested in a furnace installation depends on regularity and quantity of output of heated material. Cost of maintenance, M, depends on furnace temperature, furnace design, selection of refractories, care used in operation, and cost per unit of labor and materials used in repairs. Cost of operating labor, L, depends on regularity of production with regard to continuous output, size and shape of stock, and the provision of labor-saving equipment conjointly with unit cost of labor per hour. Cost of fuel or energy, F, depends on heating temperature, heating process, unit cost of fuel or energy, furnace design, and care used in operation. Frequently the importance of fuel cost is overemphasized at the expense of the other items (including quality of finished product), because it is more readily amenable to calculation and measurement.

DISTRIBUTION OF HEAT. The potential heat energy of the fuel (or other sources of heat) is distributed as follows:

Useful Heat in the Charge. (See Fig. 1.) If ceramic materials are the charge, their mean specific heat from room temperature to furnace temperature is used, including driving off the water of crystallization. Chemical changes, like expelling carbon dioxide, are also employed.

Heat Unavailably Stored in Furnace Walls. In furnaces that operate only during the day and are cooled down overnight much heat is lost by storage in (and, later, by dissipation from) the firebrick walls. Table 2 roughly conveys this loss.

Table 2. Heat Stored in Firebrick Walls and Conducted through Walls during Heating-up Period in Btu per Square Foot of Hearth

Type of Furnace	Heat Loss, Btu/sq ft
Continuous-pusher type	125,000
Small forge furnace	60,000
In-and-out, 2500 F after 12-hr shutdown	360,000
Same, after 50-hr shutdown	500,000

This loss is one of the reasons why furnace builders cannot guarantee fuel economy unless all operating conditions are known. For intermittent heating, the use of insulating refractories is advisable. Furnace temperature is reached in 30 to 35% of the time needed with firebrick walls, and heat loss is reduced correspondingly. In furnaces that are shut down overnight, insulating refractories save almost one-third of the total fuel.

Heat Losses through Solid Walls. Figure 2 contains information on this loss. In practice, the loss is up to 20% greater, because cracks open up between the bricks, and the thermal conductivity of the bricks changes with time. For heat losses through hearths and to water-cooled parts, see the references.

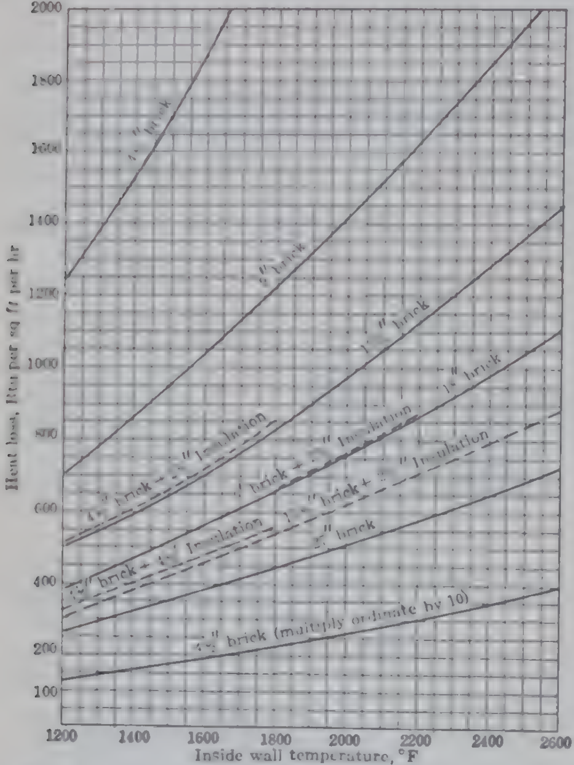

Fig. 2. Heat loss through furnace walls. (Reproduced by permission from *Industrial Furnaces*, by W. Trinks, Vol. 1, John Wiley and Sons, 1934)

Heat loss from containers and conveyors passing through the furnace equals weight times temperature rise, times mean specific heat.

Heat radiated through openings in the furnace walls equals black body radiation (for which see *Power* Volume of Kent's *Mechanical Engineers' Handbook*) through the opening multiplied by a factor which is a function of the ratio (least width of opening) divided by thickness of wall at opening. Average values are:

Ratio	0.25	1.0	4.0
Factor	0.3	0.6	0.86

Unconsumed Combustible in Refuse. This loss occurs only in coal-fired furnaces. Coal-fired industrial furnaces are very little used in the United States.

Unconsumed Combustible in Stack Gases. With automatic control of fuel-to-air ratio this loss is small, seldom exceeding 4% of the lower heating value of oil or gas. The loss is greater if coal is burned on the grate. The loss is very great in coal-fired brick kilns of the periodic type.

Sensible Heat in Stack Gases. This loss varies with furnace temperature, type of fuel, and amount of excess air. Average values (including a small amount of unconsumed combustible) are given in Table 3. The products of combustion of lean fuels (blast furnace or producer gas) carry away an even greater fraction of heat than is indicated by Table 3.

Table 3. Sensible Heat (Fraction of Lower Heating Value) in Products of Combustion

Temperature of gases, °F	1000	1200	1400	1600	1800	2000	2300
Percentage of lower heating value	26	31	36	42	47	53	62

Heat conducted through resistor terminals in electric furnaces or through part of the charge projecting into the open becomes a sizable loss at furnace temperatures of 2200 F and above. For its calculation, see the references at the end of this chapter.

The consumption of fuel per unit weight of material heated can be computed by detailed calculation of each of the eight losses. Although this method is followed for new, large furnaces, the fuel consumption of most furnaces is determined by comparison with that of existing similar furnaces. Table 4 contains average values of fuel consumption. On account of the influence which the eight losses have and because of the human element, the fuel consumption may be as low as 60% of the values in the table, or it may exceed them by 100%.

CAPACITY OF FURNACES. The number of furnaces required to heat a given weight of metal to a given temperature in a given time and the size of each furnace depend on a number of variables, such as: (1) thermal conductivity and specific heat of metal; (2) requirements for uniformity of temperature in charge; (3) rate at which heat may be applied without injury to stock; (4) ratio of surface of charge to mass; (5) ratio of surface of furnace

Table 4. Average Fuel Consumption of Industrial Furnaces

(Material heated is steel excepted where otherwise noted.)

Type of Furnace and Operation	Highest Temperature to Which Stock Is Heated, °F	Btu in Fuel per Pound of Material Heated	Thermal Efficiency, %
Drop-forging or bolt-heading furnace, oil fuel	2300	3200	11
Bolt-heading furnace, coal fired	2100	6000	6
Ingot-forging furnace, in-and-out type, oil fired	2200	2500	14
Ingot-forging furnace, in-and-out type, regenerative, gas fired	2200	1900	18
Mill-type continuous furnace	2200	1100	32
Mill-type continuous furnace, recuperative	2200	900	39

interior to exposed surface of charge; (6) state of subdivision of charge; (7) circulation of furnace gases; (8) method of heat liberation and size of heat-liberating devices; (9) cycle of operation of heating process; (10) arrangement of charge in furnace; and (11) radiation of furnace gases. In determining number and size of furnaces, total required hearth area is calculated either from the above given variables or from the following rules. It is then subdivided into standard-size units to suit plant conditions.

In the commonly used method of industrial heating, furnace temperature exceeds final temperature of charge by 50 to 125 F. Under that condition, heat "penetrates" into iron or steel at the rate of $^1/_8$ in. in 5 min. This means that a plate $^1/_4$ in. thick, standing upright in a furnace, is heated with sufficient uniformity in 5 min. This rule was derived from forging practice and is sufficiently accurate as long as furnace temperature is not much higher or lower than forging temperature. For brass, temperatures are equalized twice as fast, for aluminum six times as fast, and for copper nine times as fast as for steel; but, in spite of this fact, the rate at which these metals can be heated, per square foot of furnace hearth area per hour, usually is less than for steel which is being heated to forging temperature. Reasons are:

1. The nonferrous metals are heated to temperatures much below 2200 F. At low temperatures, radiation from furnace gases and from electrical resistors is weak compared to radiation at high temperatures. If steel is heated to 1400 F, the rate of heating is about one-half of the 2200 F rate. The absorption of radiant heat is reduced by the smooth, bright surface of most nonferrous metals. Black copper surfaces, however, absorb heat almost as rapidly as oxidized steel surfaces.

2. Forging ingots are heated at the rate of 16 to 20 min per in. diameter, if of soft steel, and at the rate of 30 to 40 min per in. of diameter, if of "tender" steel. Certain steels are very sensitive to temperature changes at "blue brittleness" (around 500 to 800 F). Above dull red heat, they cannot be injured by rapid heating. When a new alloy is to be heated, experimenting is necessary in order to find the safe rate of heating.

3. In ordinary furnaces, steel can be heated at the rate of 25 to 35 lb per sq ft of hearth area per hr for heat-treating; at the rate of 60 lb for annealing; 80 lb for uniform-temperature forging and rolling; and 110 to 130 lb for work in which 40 F temperature difference per in. of thickness of stock is allowable.

4. Steel bars for drop forging can be heated at the rate of 5 to 10 min per in. of diameter.

5. The time for heating plus soaking grows more rapidly than the diameter of the piece being heated because the soaking time is roughly proportional to the square of the diameter. Very large forging ingots (in excess of 100 in. in diameter) require up to 80 min per in. of diameter.

The heating time is shortened materially if the cold charge is heated just as rapidly as possible without injury to the charge until the surface temperature of the charge slightly exceeds the desired final temperature. The furnace temperature is then dropped slightly below the desired final temperature of the charge. Equalization of temperature in the charge, if it is solid and without voids, takes place quickly. The effect of high furnace temperatures upon the rate of heating square steel bars (between 1 and 5 in. in diameter) is illustrated by Fig. 3. Depending on the material being heated, heating plus soaking can be accomplished in 30 to 70% of the time required with constant furnace temperature. In continuous furnaces, this heating method is accomplished by a very hot heating compartment and a cooler soaking zone. When a new alloy or a ceramic material is to be heated by this method, experimentation is necessary to find the highest rate of heat input that the material can endure without injury.

6. Coiled or piled material requires from 80 to 200 min per in. of thickness, if heat is applied from both sides. The wide variation is caused by the number of air spaces per inch in the charge, by the number of contact points, and by the heat flowing in at the edges of sheets.

Heat Liberation. For limits of heat liberation in electrically heated furnaces, see the chapter on industrial electric heating, which follows this one.

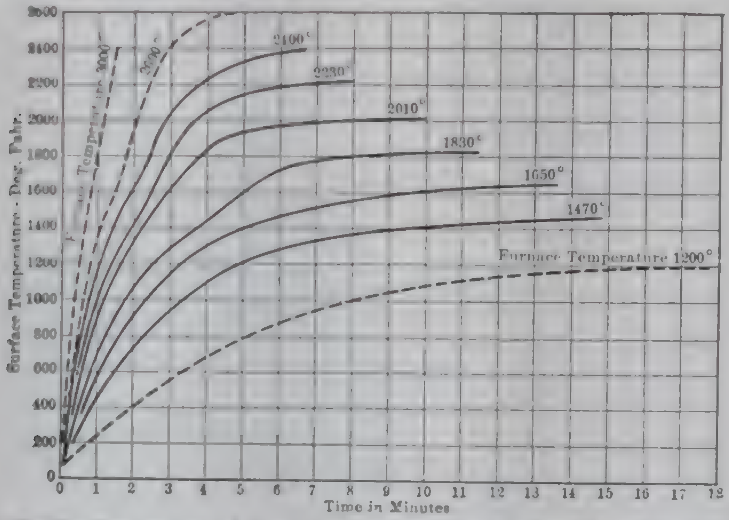

FIG. 3. Heating time per inch of diameter, square steel bars, at various furnace temperatures.

In furnaces of the combustion type, from 1.5 to 100 Btu are liberated per cubic foot of combustion space per second. The low value applies to very poor mixing of fuel and air, very imperfect utilization of volume of combustion chamber by flame or gas jets, coarse fuel, and cold air. The high value is attained by thorough mixing of fuel and air, perfect utilization of combustion space, very fine atomization or powdering of fuel, and preheating of air to 1000 F. Even higher rates are attained in modern cup burners in which temperatures in the neighborhood of 3000 F are carried.

FLUES AND PORTS. If furnaces are properly proportioned, the following port sizes are approximately correct, based on steel as stock to be heated, and for 100 lb per sq ft of hearth per hr. If a smaller quantity is to be heated, the outlet flues should be partly covered by bricks.

Temperature of furnace, °F	1400	1800	2200
Port area, sq in. per sq ft of hearth	2.0	3.5	7.3

These figures hold for batch-type furnaces of medium size without recuperation or regeneration. For large and important furnaces, the ports and flues must be calculated on the basis of flue gas quantity in unit time and pressure drop.

MATERIALS OF CONSTRUCTION FOR FURNACES. The most commonly used material is firebrick (see also Section 5), either solid or porous. The porous form is called insulating firebrick and is weaker than solid firebrick but lighter and, therefore, carries less superimposed load. High-alumina bricks withstand higher temperatures than ordinary firebrick.

If furnaces heating steel for forging or rolling are driven hard, the scale softens and forms ferrosilicate (slag) with firebrick or sand. Formation of slag is avoided, if hearths are made of chromite or magnesite. If the furnace temperature does not exceed 2300 F, no slag is formed, even with firebrick hearths. Silicon carbide serves for muffles (enclosing the charge or the flame), for baffles, and for hearth rollers. Cast iron serves for doors, for door frames, and for hearth plates of furnaces carrying not more than 1600 F. Plain carbon steel is used for binding and occasionally for door frames. Heat-resisting alloys serve for hearth chains, hearth rollers, muffles, containers, electrical resistors, and other parts subjected to furnace heat. The higher the temperature to which they are subjected, the higher must be the content of chromium, nickel, and other alloying elements. At high temperatures even the best alloys creep under stress and have a limited life.

2. FUELS

SELECTION OF FUEL OR ENERGY. The cost of fuel (or other sources of heat energy) is, in many instances, an extremely small fraction of the total cost of the manufactured product, and a minor fraction of the heating cost. In such cases, the effect of the form of heat energy on the finished product is most important, and the unit cost of heat energy is not a matter of consideration. In other cases, the fuel cost is a large item in the total cost, and cheapness of fuel is the deciding factor. A skilled and careful operator can do good heating with almost any fuel. The following fuels are commonly used (see also Eshbach's *Handbook of Engineering Fundamentals* and *Power* Volume of Kent's *Mechanical Engineers' Handbook*).

Natural gas is an excellent fuel for all heating operations. In many localities it is available at low cost. Wherever uninterrupted furnace operation in cold weather is required, a standby installation is needed for burning oil, butane, casinghead gasoline, or some other fuel which can be stored because, in many industrial sections, the domestic consumer (who pays a higher rate) is given preference in cold weather.

City gas is a mixture of water gas and retort gas. Since the cost of this excellent fuel is high, its use is commonly restricted to small and medium-sized furnaces.

Water gas is a clean but very poisonous fuel which burns with a nonluminous flame. It is made in an elaborate gas generator with waste-heat boiler and automatic valve operation. A gas storage tank is also needed. This gas is useful for large installations only. The impending availability of cheap oxygen will greatly simplify the production of water gas.

Raw producer gas is the standard fuel for rough heating in large furnaces, where the higher grade fuels are not available, or where low fuel cost is an important item. Gas producers are located close to the furnaces, so as not to lose the tarry vapors by condensation in the ducts.

Cold, clean producer gas was, at one time, the standard fuel for a group of scattered factory furnaces. The steady increase in the efficiency of electric power generation has caused the more general adoption of electrically heated furnaces and has caused cold, clean producer gas to be all but abandoned.

By-product coke oven gas and **refinery gas** are seldom available at some distance from the works where they are generated. Both gases are very good fuels.

Liquefied petroleum gases, such as butane, propane, and casinghead gasoline are useful fuels wherever an uninterrupted supply is obtainable. In most localities, the cost is rather high.

Heavy Fuel Oil (Nos. 5 and 6 on the commercial scale). Number 6 is also known as Bunker C oil. Both grades are the residuum left from distillation or cracking. These oils must be preheated and must flow continuously past the burners in a ring-type piping system. They are very good for rough heating.

Light Fuel Oil (No. 3 on the commercial scale; there is no No. 4). This oil is a distillate and needs no preheating. It is also known as gas oil or as diesel oil. It costs more than heavy fuel oil. Number 2 oil is also used occasionally.

Bituminous coal is seldom burned on grates or stokers of industrial furnaces in the United States, except in so-called air furnaces, which lie outside the scope of this section. Coke is occasionally burned under core ovens in foundries. Solid fuels are burned in industrial furnaces in some European countries where cheap labor as well as willing and attentive craftsmanship is available.

Powdered coal is useful in large furnaces only, because satisfactory small individual pulverizers have not yet been developed for powdering coal (at reasonable cost) to sufficient fineness for combustion in industrial furnaces of average size. If powdered coal is burned in small furnaces, unburned coke particles and ash are discharged into the workshop and into the stack.

Coal tar is available in steel works only. It is similar to No. 6 oil but is more difficult to handle. Topped tar is coal tar from which the tarry acids have been removed.

Electrical energy takes the place of fuel in many heating operations. The ever-increasing size of turbines and generators and the utilization of high steam pressures and temperatures have reduced the cost of labor and fuel to such an extent that electrical energy can compete with fuel in industrial furnaces up to 1800 F. Moreover, electrically heated furnaces can be placed in the production line without discomfort to the workers in the shop.

3. HEAT SALVAGE

Heat salvage, although very desirable from the standpoint of conservation of national resources, always leads to complications and is, for that reason, practiced on large furnaces only.

Wall losses, in a continuously operated furnace, can be considerably reduced by thick walls and insulation, provided the wall material does not sag or melt at furnace temperatures. The loss to water-cooled parts is reduced by covering the parts with refractory material as much as possible. This loss is also reduced by circulating distilled water through the parts and cooling it by raw water in a separate cooler. In that manner, water temperatures up to 190 F can be used without deposits of lime in the tubes.

Regenerators are piles of brick which are alternately heated by outgoing products of combustion and cooled by incoming combustion air, whereby the latter is preheated. As a rule, direction of flame in the furnace also alternates. Furnaces with regenerators become part of the building. Regenerators are in use in comparatively few furnaces, mostly under those in which heavy pieces of steel are heated. As a rule, the shape and weight of these pieces changes from time to time.

Recuperators are heat exchangers in which heat flows in a steady stream, through a partition, from hot products of combustion to cooler, incoming combustion air. Many industrial furnaces do not readily lend themselves to heat salvage by recuperators. For forging and rolling temperatures (2200 F), this dilemma exists: Refractory recuperators eventually spring leaks, but most metallic recuperators burn out. The latter misfortune is avoided by mixing cold air with the outgoing products of combustion under control of a thermostat.

Heat in chain conveyors is salvaged by keeping the chain in the furnace during the return travel. In tunnel kilns, the heat in both the outgoing products and in products of combustion is largely recovered by preheating the incoming products and also the combustion air.

4. COMBUSTION DEVICES

BURNERS for gas and oil have been developed to a high state of perfection. Their selection may well be left to the furnace builder, because the burner must be adapted to the furnace with which it is to be used. Burners must be so designed and so located in the furnace walls that the charge is uniformly heated at all points of the hearth. Burners must permit adjustment of furnace atmosphere from excess air to deficiency of air.

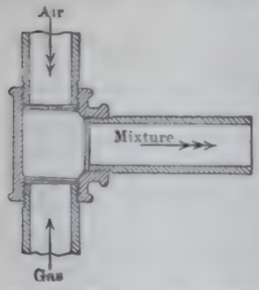

FIG. 4. Tee-mixing burner for gas.

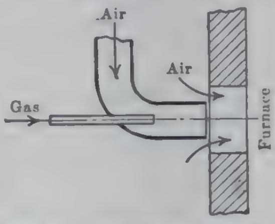

FIG. 5. Burner with gas and part of air under pressure.

Gas burners are mixers of gas and air. The mixing is obtained by gas and air impinging upon each other (Fig. 4), by turbulent flow in a pipe (Fig. 5), or by inspiration (Fig. 6). Burners of the inspirator type are very common. However, their turndown is limited, not only because the air-to-gas ratio changes, but also because the flame creeps back and causes backfires. Flames carrying unconsumed carbon particles are luminous and transmit more heat by radiation than nonluminous gases of the same temperature. For that reason, luminous-flame burners are much used. Such a burner is illustrated in Fig. 7. As a rule, raw producer gas is admitted to the furnace through ports of refractory material, which alternate with ports through which air is admitted. Such ports do not permit adjustment of flame length. Burners are on the market which, when using raw producer gas, permit adjustment of flame length and of furnace atmosphere.

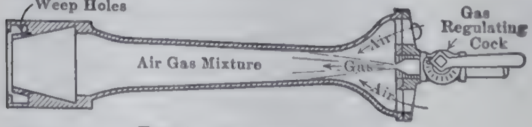

FIG. 6. Inspirator gas burner.

Oil burners are mainly oil atomizers; some burners also mix the atomized oil with combustion air. Atomization is never obtained by oil pressure alone, because fineness of atomization suffers when the burner is turned down. Three methods of atomization are in use:

1. **By steam or air at high pressure. This method is preferred when a long flame must be given direction.** A burner of this type is shown in Fig. 8.

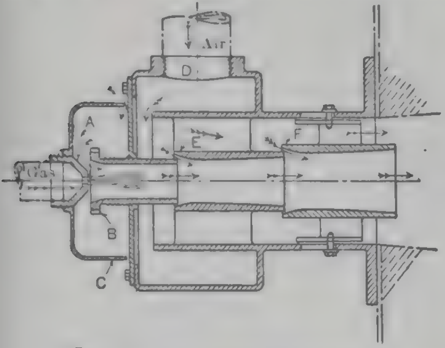

Fig. 7. Luminous-flame burner.

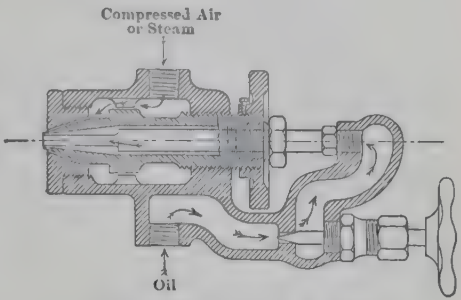

Fig. 8. High-pressure oil burner.

2. By air of 1 to 5 psi pressure and by oil pressure of 30 to 90 psi, the high oil pressures going with low air pressures. These burners are called low-pressure burners. Examples are shown in Fig. 9.

3. By fan blast of $^1/_4$ to 1 psi and oil pressure of 30 to 150 psi, the high oil pressure again going with the low air pressure. This method of atomization is shown diagrammatically in Fig. 10. The rotary burners that are frequently applied to steam boilers and water heaters fail, if applied to industrial furnaces, because of the high-temperature heat which is radiated from the furnace interior to the burner.

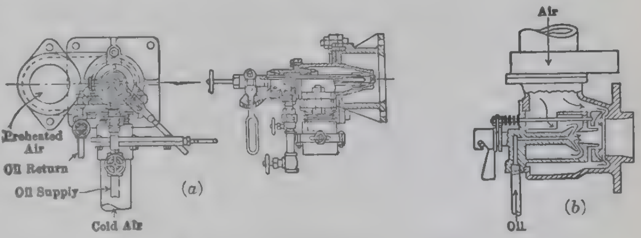

Fig. 9. Low-pressure oil burners.

Burners for powdered coal consist of two pipes, one for coal and one for air. The characteristics of the powdered coal flame depend mainly on the size of the coal particles and on turbulence in the furnace.

Grates and stokers serving industrial furnaces do not differ from those used for other purposes, with the exception that air and steam are blown under the grate into the closed ashpit whereby the grate or stoker becomes a gas producer and some pressure can be maintained on the furnace hearth.

LABOR-SAVING EQUIPMENT. In many factories, rising costs of labor make the cost of fuel (or electrical energy) a secondary consideration and put labor saving in the first place. Labor is saved by charging (and discharging) machines, by continuous furnaces of the pusher type, by furnaces with rotating hearth, and by so-called automatic furnaces, through which the material to be heated is conveyed by mechanical means. The suitability of the various conveying devices depends largely on the furnace temperature. Up to 1200 F (with careful design, up to 1400 F), the chain conveyor with solid links or woven wire mesh is satisfactory. Up to 1800 F, rocker bars (walking beams) and driven rollers of heat-resisting metal are suitable. Up to 2300 F (but not above), rollers of silicon carbide have given a good account of themselves. For still higher temperatures, the pusher-type continuous furnace, the rotating-hearth furnace, and the batch-type furnace with charging machine serve well. Materials handling equipment may be employed for bringing pieces to the furnace and conveying them after discharge from the furnace.

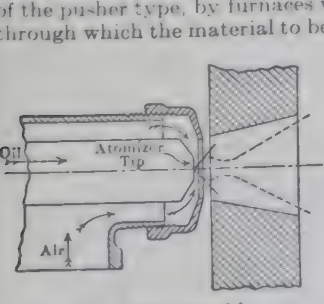

Fig. 10. Fan-blast oil burner.

TEMPERATURE CONTROL. Automatic devices are often installed for controlling the furnace temperature, usually for keeping it constant, but occasionally for varying it with time according to a set program. The measuring device is a thermocouple which actuates a millivoltmeter. Deviation from the correct position is amplified either mechanically by the depressor-bar method, or electrically by electronic tubes. The energy set free by the relay interrupts or alters the supply of electrical energy in electrically heated furnaces or adjusts the opening of fuel valves and of air valves in fuel-fired furnaces. Temperature controllers have been developed to a high state of perfection. However, they control the temperature of the furnace, not the temperature of the charge. More specifically, they control the temperature of that spot of the furnace where the thermocouple is located (or which is "seen" by a radiation pyrometer). On account of this fact, the best temperature control instrument must fail if improperly applied. Two types of temperature control are in use (1) the all-on and almost all-off type, and (2) the proportional type, in which the supply of fuel and air is gradually adjusted over the range between minimum and maximum. For small furnaces, the temperature control costs more than the furnace. An inexpensive and yet reliable temperature control instrument is much needed.

FURNACE ATMOSPHERE. Oxygen, carbon dioxide, water vapor, and sulfur form scale on the metals that are ordinarily heated in industrial furnaces. The surface of steel is decarburized by the first three of the foregoing gases. Carbon monoxide and hydrogen counteract the formation of scale. Rate of scale formation is a function of chemical equilibrium between charge and furnace atmosphere. That equilibrium varies with furnace temperature. If fuel is burned with a deficiency of air, scale formation is reduced, but not eliminated, unless the deficiency of air is so great that an uneconomically great portion of the fuel passes out into the stack.

Natural atmospheres are controlled by maintaining a fixed but adjustable ratio between fuel and air. Devices serving this purpose are on the market for gaseous and for liquid fuels.

If the charge is to be heated without formation of any scale, artificial or "prepared" atmospheres surround the charge. Such prepared atmospheres consist of hydrogen, nitrogen, carbon monoxide, or a mixture of these gases. Lithium vapor is also used. A common method for producing artificial atmosphere is to burn natural gas or city gas in insufficient air, and to freeze water out of the products of incomplete combustion. Another method is based on the thermal decomposition of ammonia. Generators embodying these principles are expensive and for that reason are applied mainly to large furnaces. In fuel-fired furnaces, the charge rests in (or moves through) a muffle which is filled with prepared atmosphere. In electrically heated furnaces, muffles are, as a rule, not needed. In small electric furnaces for tool hardening and similar work, where the door must remain partly open most of the time, a nonoxidizing atmosphere is maintained in the furnace by providing inside the door opening a gas-flame curtain, as shown in Fig. 11. For bright annealing of copper or brass, an atmosphere of steam is frequently used. A regularly renewed supply of charcoal or petroleum coke helps to prevent oxidation and decarburization. For nitriding, the atmosphere consists of ammonia. For gas-carburizing, a carbon-rich gas such as propane is introduced into the furnace muffle.

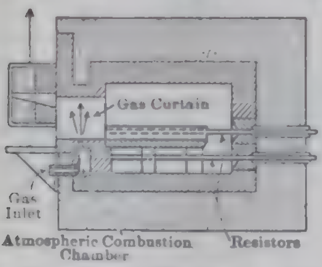

FIG. 11. Tool-hardening furnace with gas curtain.

All salt baths are prepared atmospheres, in the extended sense of that word. For a description of the large number of different salts which are used in industrial heating, see the references at the end of this chapter.

5. TYPES AND SELECTION OF FURNACES

Furnaces purchased for the purpose of heating one kind of part or material are often used later on to heat parts of another kind or are operated at another temperature. Furnaces designed for fuel of one kind are often fired, later on, by fuel of another kind. Furnaces intended for continuous operation throughout the week may be operated only eight hours each day in times of depression. For these reasons, extreme specialization in furnace types is advisable only where a long-continued demand for goods of the same material, weight, and shape is likely to exist.

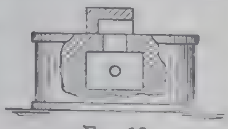

FIG. 12

There are between 90 and 100 different types of furnaces in use. Only the most important types are mentioned here. Although the blacksmith's coal fire is still found occasionally, gas- or oil-heated furnaces, as shown in Figs. 12, 13, and 14 are preferred. For more specialized work, the types shown in Figs. 15 or 16 are common. Coal-fired furnaces (with steam and air blown into the ashpit) for general forge work are built as in Fig. 17, with an end slot or else with a side door. Heat-treating furnaces are often underfired.

for the sake of having a hot hearth, as in Fig. 18. For pack hardening, the hearths of underfired furnaces are often perforated, for greater uniformity of temperature. Tool-hardening furnaces usually have a preheating chamber above the main heating chamber (Fig. 19). Furnaces for heavy or bulky material are of the car type. If oil serves as fuel, they are either sidefired, as in Fig. 20, or overfired, as in Fig. 21. With gas-firing, the burners either point directly into the heating chamber or else fire behind muffle walls. The car top is cold; hence, the charge must be blocked up above the hearth. Automatic-conveyor furnaces, with the conveyor returning either below the furnace, as in Fig. 22, or else in the furnace, are used for quantity heating of comparatively light material. Drum furnaces (Fig. 23) are used for small and light pieces. They also serve for gas carburizing. Furnaces with roller conveyors (Fig. 24) are practical for flat or long pieces that cannot fall between the rollers. Rocker-bar (intermittent-conveyor) furnaces (Fig. 25) are much used for heat treating wide material, such as automobile axles. Furnaces with rotating hearths (Fig. 26) have grown enormously in popularity and have been built with hearth diameters in excess of 60 ft.

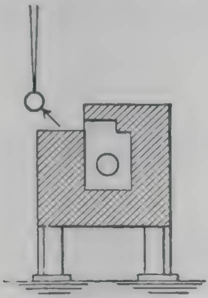

Fig. 14

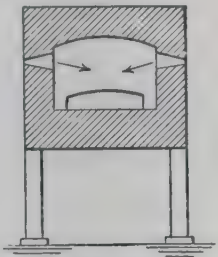

Fig. 15

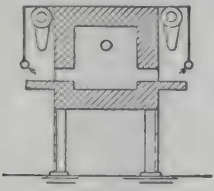

Fig. 16

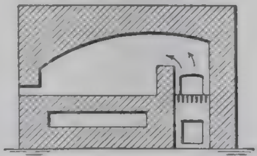

Fig. 17. Coal-fired furnace.

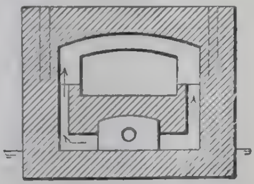

Fig. 18. Underfired furnace.

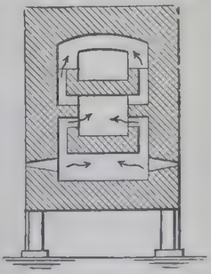

Fig. 19. Furnace with preheating chamber above main heating chamber.

Nonferrous metals are frequently bright annealed in steam or in a reducing atmosphere of products of combustion, as shown in Fig. 27. Any furnace of the muffle type can be used for bright-annealing steel, if the muffle is filled with a prepared, protective atmosphere (see p. 22-10). In electrically heated furnaces, bright-annealing is done without a muffle. A much-used furnace for bright-annealing flat sheets is illustrated in Fig. 28.

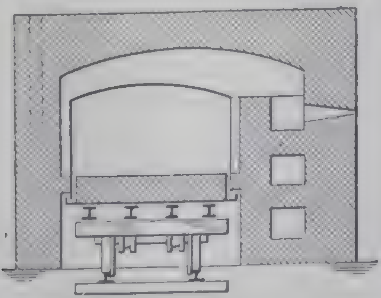

Fig. 20. Sidefired furnace.

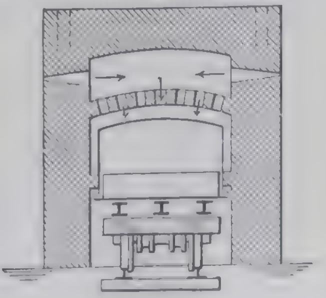

Fig. 21. Overfired furnace.

Gas is burned in radiant tubes which are muffles for the flames while sheets are piled in an inner cover or annealing box filled with prepared, deoxidizing atmosphere (abbreviated "deox"). If direct firing is employed instead of radiant tubes, the outside of the annealing box is given a protective coating against rapid oxidation. The same principle is employed for bright-annealing coils of strip steel. They are stacked, and a cylindrical annealing box covers them. Deoxidizing gas is circulated by a fan up through the hole of the coils and down along the outer circumference. This furnace is built either with radiant tubes or with direct firing. Pot furnaces (Fig. 29) likewise conserve a bright finish on the charge. Filled with lead or one of many different salts, they are much used in the tool industry. Cyanide pot furnaces for carburizing (Fig. 30) are always equipped with a hood and a connection to the stack, for the purpose of carrying poisonous fumes off into the open.

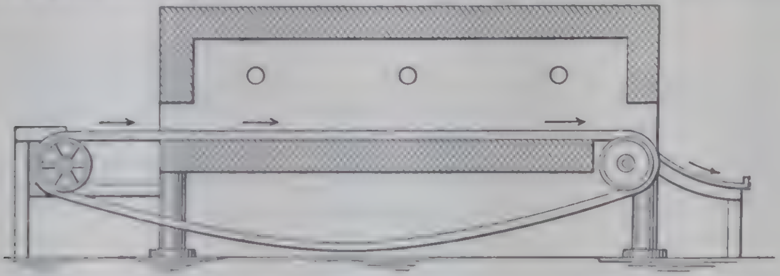

Fig. 22. Automatic conveyor furnace.

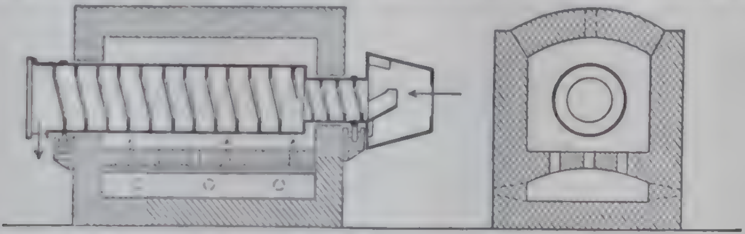

Fig. 23. Rotary cylindrical furnace.

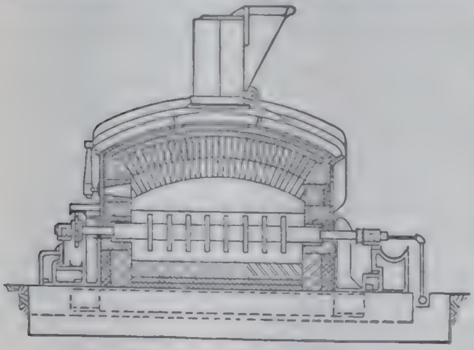

Fig. 24. Roller conveyor furnace.

A typical furnace with recirculation of furnace gases is illustrated in Fig. 31. It serves for maintaining a very uniform temperature in the charge at low furnace temperatures.

In steel works and forges for heavy material, pit furnaces are used for reheating ingots, and continuous furnaces of the pusher type serve for heating heavy blooms and billets. (See Fig. 32.)

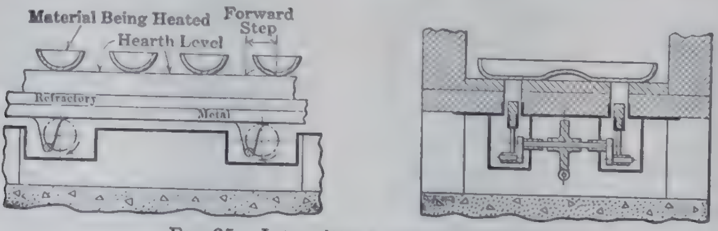

Fig. 25. Intermittent conveyor furnace.

Although electrically heated furnaces are the subject of the following chapter, they are mentioned here for the sake of completeness in the listing of furnace types. Although

the source of heat in electric furnaces costs two to four times as much as it does in fuel-fired furnaces, electrically heated furnaces are often preferred for the following reasons: They discharge no obnoxious gases into the workroom; they can be placed anywhere in the production line; and they are easily moved from place to place. In order to conserve expensive heat, they are usually so well insulated that workers near the furnace are not inconvenienced by heat. At one-half cent per kilowatthour, the cost of electrical energy is, on the average, in the neighborhood of 1% of the cost of the finished article and is, therefore, not a burden. Electric-resistor furnaces are not recommended for the temperatures required for forging or rolling of steel. Suitable resistor material is not available, and resistor terminals are troublesome. Heating by high-frequency induction has been very successful for bars up to 4 in. in diameter or square. Although the efficiency (heat imparted to steel divided by heat equivalent of kilowatthours) is only 50%, the heating time is so short that practically no scale is formed. The heating process is a function of automatically controlled time, and all pieces are heated absolutely alike and uniformly. For solid metals of larger dimensions, induction heating offers no advantages.

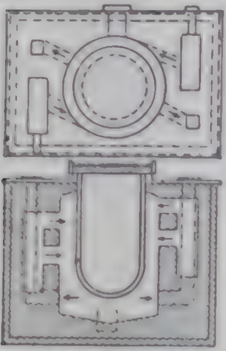

Fig. 29. Deep pot furnace, sidefired on two levels. (Reproduced by permission from Trinks, *op. cit.*)

EXAMPLE OF FURNACE CALCULATION. Furnace is required for heat-treating small steel parts, at the rate of 500 lb per hr. Furnace is of the underfired type (Fig. 18). Temperature of furnace = 1450 F. From Fig. 1, increase of heat content from 60 to 1450 F = (222 − 6) = 216 Btu per lb. For steel, the heat content is actually slightly higher than this value, which applies to pure iron. From Table 4, the thermal efficiency of the given type of furnace under average conditions = 19%. Heat required in fuel per pound of steel = 216/0.19 = 1140 Btu. If the fuel to be used is oil of 140,000 Btu per gal, the fuel consumption is (500 × 1140)/140,000 = 4.1 gal per hr.

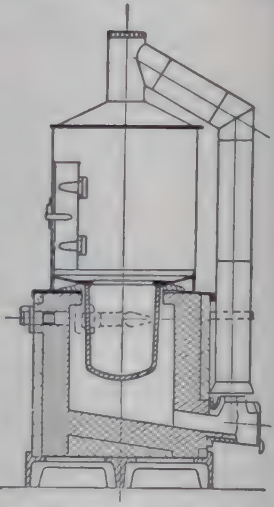

Fig. 30. Pot furnace for salt bath. (Reproduced by permission from Trinks, *op. cit.*)

From Rule 3, p. 22-05, the rate of heating will be about 30 lb per hr per sq ft of hearth. Required area of hearth = 500/30 = 16.7 ft. The shape of the hearth and height of the heating chamber are determined by the size of the pieces and the method of charging, or in some cases by the nearest standard sizes of the furnace builders.

Taking the rate of heat liberation by combustion as 12 Btu per cu ft per sec, the volume of combustion space required is (500 × 1140) ÷ (3600 × 12) = 13.2 cu ft. The height of chamber required to give this volume of combustion space depends on the shape and size of hearth supports, but would approximate 15 in. The rate of 12 Btu per cu ft per sec is somewhat high for the combustion of fuel oil with burners of the usual type, but this simply means that part of the combustion takes place in the upper or heating chamber. No harm is caused thereby.

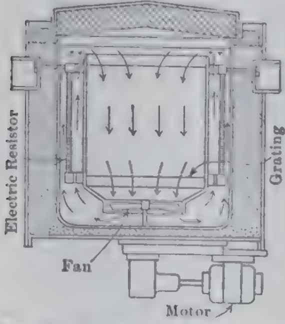

Fig. 31. Convection type electric furnace.

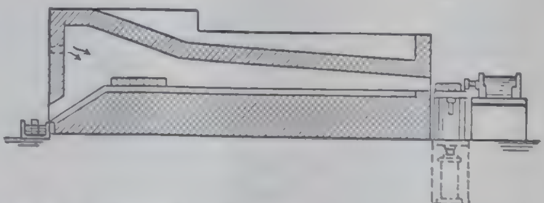

Fig. 32. Continuous furnace with end discharge. (Reproduced by permission from Trinks, *op. cit.*)

From the table of flue sizes (see p. 22-06), the area of flue openings required for furnace temperature of 1400 F = 2.0 sq in. per sq ft of hearth; for 1450 F furnace temperature, it would be somewhat more, or about 2.5 sq in. Hence, $2.5 \times 16.7 = 42$ sq in., total area of flues. The flue dimensions are made multiples of 2 $^{1}/_{2}$ in. and 4 $^{1}/_{2}$ in.

The size of doors is determined by the size and shape of heating stock and the method of charging.

INDUSTRIAL ELECTRIC HEATING

By R. M. Cherry

Electric heat may replace fuel and steam advantageously in many industrial heating processes because the heat generated by electricity usually can be applied at a higher efficiency than is realized with fuel. Its application for heating often results in increased production, a better quality of work, and in many cases lower overall costs.

Whether or not electric heating is used for a given application depends on the complete cost analysis, including such factors as cost of heat, quality of product, labor of attendants, subsequent operations, working conditions, complaints, rejects, etc.

Industrial electric heating gives perfect heat distribution and permits great flexibility in temperature control. Automatic control is recommended for practically all applications, as it not only gives better control of temperature and heat distribution, but also eliminates the labor of attendants, removes the danger of spoilage, and insures that parts subjected to heat receive exactly the same treatment, thereby producing uniform results.

In general, industrial electric heating is classified as:

1. Industrial heaters and devices for such applications as small ovens, heating of watchmen's houses, crane cabs, soft-metal melting pots, liquid heating, glue pots, process machinery, etc.
2. Ovens for baking, drying, etc.
3. Resistance furnaces for heat-treating metals, porcelain enameling, etc.
4. Melting furnaces for melting steel, copper, and brass.
5. Induction heating.
6. Dielectric heating.

6. INDUSTRIAL HEATERS AND DEVICES

Manufacturers' catalogs contain fairly complete information on small heating units and devices, method of application, and determination of type, size, and rating of the units required for a particular service.

Industrial heaters and devices are, in general, classified as air heating, liquid heating, and contact heating. For these applications, there are various types, sizes, and ratings of standard heaters, generally known as strip heaters, tubular-type heaters, and cartridge heaters.

STRIP HEATERS are used principally for air heating and contact heating. They consist of an outer metal sheath with the coiled resistance wire electrically insulated from the outer sheath and provided with suitable terminals. These heaters are usually approximately 1 $^{1}/_{2}$ in. wide and $^{1}/_{2}$ in. thick or less, and they are available in standard lengths from approximately 7 in. up to 4 ft. They are used principally for heating watchmen's houses, crane cabs, valve houses, isolated rooms, small ovens, pump houses, ticket booths, process machinery, etc.

TUBULAR-TYPE HEATERS are used principally for liquid heating and contact heating. They comprise a tubular outer metal sheath in which the resistance wire, electrically insulated from the outer sheath, is coiled. The outer sheath material may be steel, nickel, copper, stainless steel, Monel metal, etc., depending on the application of the unit. This type of unit can be formed into almost any desired shape. Also, it may be cast into gray iron, alloy iron, aluminum, or other metals. Such cast-in units provide a large area in contact with the liquid to be heated and form a mechanically strong unit.

Tubular units, either of the plain sheath type or cast-in type, are used principally for heating such liquids as water, oils, paraffin, alkaline baths, nickel-, copper-, or chrome-plating bath solutions, and mild sulfuric acid solutions up to 10% concentration, if no other acids are present; for melting soft metals, as tin, lead, solder, babbitt, type metal, and similar alloys; and for heating salt baths to temperatures up to approximately 1100 F. Locating the heating units directly in the liquid to be heated gives a maximum efficiency of heating in that all the heat is generated in the liquid itself; also, this method of applying heat provides for the best possible temperature control.

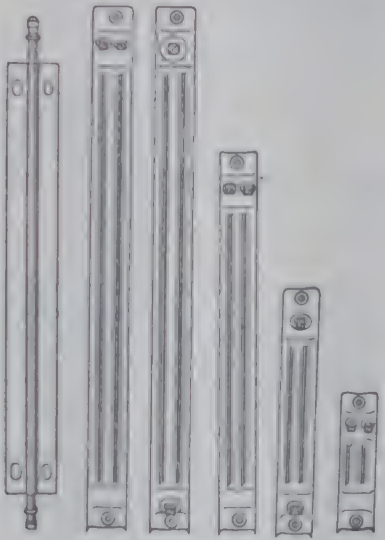

FIG. 1. Strip heaters.

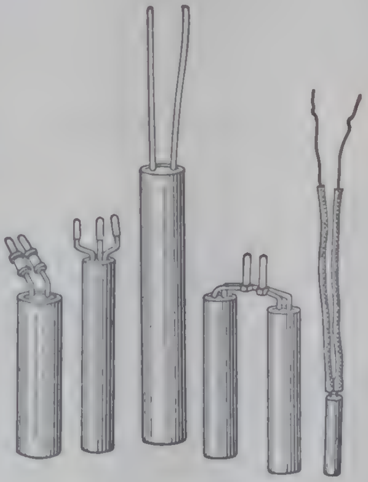

FIG. 2. Cartridge heaters.

The tubular-type heating unit is made in sizes varying from approximately $^1/_4$ to $^3/_4$ in. in diameter and from 2 to 20 ft long. The size and rating depend on the application.

CARTRIDGE HEATERS. Cartridge heating units are used principally for contact heating. The construction is similar to that of the tubular unit in that it consists of an outer shell of metal and coiled resistance wire suitably insulated from the outer shell. The two terminals of the heating unit are brought out at one end. Cartridge heaters are used where small quantities of heat are required at a definite location. They are applied usually by drilling a hole in the part to be heated and inserting the heating unit.

Cartridge heating units are available in sizes from $^3/_8$ in. in outside diameter by 1 $^1/_2$ in. long to approximately 1 $^1/_4$ in. in outside diameter by 8 $^1/_2$ in. long. Ratings range from 50 watts in the smaller size up to approximately 1200 watts in the larger size. These ratings are based on a sheath material of brass. Cartridge heating units also are available with an alloy steel sheath, suitable for a maximum sheath temperature of 1200 F. The electrical rating for these units is approximately 50% higher than those listed above.

Typical heaters are shown in Figs. 1, 2, and 3. Figure 1 shows several forms of strip heaters, and Fig. 2 various arrangements of cartridge heaters. Figure 3 illustrates a number of varieties of liquid heating units, technically known as immersion units. As shown, the units may terminate in a pipe fitting which may be screwed into the wall of the chamber containing the fluid to be heated. Typical methods of application of the strip, tubular, and cartridge units are shown in Figs. 4, 5, and 6.

7. OVENS FOR BAKING AND DRYING

Electric ovens are widely used for many industrial applications. Examples are core baking, paint drying, japanning, bread and cake baking, and baking of such electrical parts as armatures and coils.

Batch-type ovens are used principally for small production. A typical batch oven is the box type, with a door at one or both ends. The material to be baked is loaded on trays, trucks, or an overhead intermittently operated conveyor.

Continuous ovens are used for quantity production. Typical continuous ovens are the straight-through conveyor type, the straight-through conveyor oven with ventilating air passing counterflow to the work, or the continuous counterflow oven where outgoing hot material preheats incoming cold work. The electrical equipment for such ovens consists of standard types of oven heaters and suitable automatic control equipment. The heaters may be mounted on the oven walls or in a compartment outside the oven. When located inside the oven, the heater usually consists of ribbon resistors mounted on insulators which in turn are supported in a metal frame. When the outside heater compartment is used with a recirculating fan, the fin tubular heater or the edgewound ribbon-resistor heater is used.

VENTILATION is an important factor for many oven applications, such as those used for paint drying and japanning, where considerable quantities of volatiles are given off during heating. The amount of ventilation required depends on the size of oven, the size and surface area of parts being baked, and the amount of volatiles to be driven off. Most of the volatiles are driven off during the first part of the heating cycle. Therefore, in a continuous oven they must be removed near the entrance to the oven. All dipped or sprayed parts should be allowed to drip thoroughly before being placed in the oven.

ENERGY REQUIRED for the baking of particular parts depends on the production and the size and type of oven. The approximate energy required for various applications is as follows:

Application	Japanning		Core baking		Bread baking
Type of oven	Batch	Continuous	Batch	Continuous	Continuous
Approx. lb/kw-hr	15–20	25–45	10–12	12–15	10–12

8. RESISTANCE FURNACES

The resistance furnace consists of a heating chamber, containing heating units, which may be mounted on the sidewalls, roof, floor, or doors, depending on the application. Heat is transmitted to the work by radiation and convection. Resistance furnaces are used for such heating applications as annealing, normalizing, hardening, drawing, carburizing, porcelain enameling, and brazing.

Heating units are principally the metallic type in rod, ribbon, or cast form, or a nonmetallic heating unit, as silicon carbide, usually in round-bar form. Nickel-chromium and nickel-chromium-iron alloys are universally used for operating temperatures up to a maximum of 2100 F, which covers the majority of industrial heating applications.

TYPES OF FURNACE. (See also pp. 22-10 to 22-14.) Many standard types of furnace are available, the selection of type and size of furnace depending on the application, production, and method of handling desired. The more common types of furnaces are:

Box-type furnace is essentially a box, with a door at one or both ends. The parts to be treated are handled by hand, either individually or in containers.

Pit furnace may be either circular or rectangular, with the opening at the top, and provided with a suitable cover.

Bell furnace may be either circular or rectangular. The material to be treated is loaded on bases, and the furnace is lifted and moved from base to base; or the furnace may be lifted and the bases moved. Bell furnaces are used either with or without an inner retort, depending on the application.

Elevator furnace may be either rectangular or circular, usually rectangular. The work is loaded on a car, which is pushed under the furnace and elevated into the furnace chamber.

Car-bottom furnace is similar to the box-type furnace, except that the hearth is mounted on wheels to permit it to be removed for loading and unloading.

Pot furnace consists of an inner metallic pot, with the heating units located outside of the pot. Pot furnaces are used principally for lead hardening, cyanide or salt hardening, and hot dip galvanizing.

Pusher furnace, in which the work is pushed through the furnace, one piece against the other where the parts can be so handled; or the parts are loaded on stools or trays, which are pushed through the furnace, one position at a time.

Rotary-hearth furnace, in which a rotating table, provided with sand seals between the rotating table and stationary part of the furnace, carries the parts to be treated. Loading and removal of work is through the same or adjacent doors, thereby providing for loading and unloading from one central point.

Roller-hearth furnace has a hearth of driven rolls, on which the material being treated is carried through the furnace. The spacing between rolls depends on the parts or trays to be handled. The rolls extend through the walls of the furnace to bearings mounted on the outside.

Conveyor furnaces are of many types, depending on the type of conveyor used, as a mesh belt, cast-link belt, monorail conveyor, etc. For such applications as hardening of steel, the conveyor should be arranged to remain in the furnace at all times to conserve heat. When the furnace is used for annealing, the parts being cooled in the furnace, the conveyor usually returns underneath it.

Catenary furnace, a continuous furnace for annealing steel strip in a protective atmosphere, consists of heating and cooling chambers. The strip is supported on rolls located outside the heating chamber so that the strip hangs in a catenary without any contact with supports in the heating chamber.

Tower furnace consists of one or more vertical heating chambers and may be equipped with one or more vertical cooling chambers. Each chamber is provided with supporting drums top and bottom. This type of furnace is used with a protective atmosphere for continuous annealing of strip.

ATMOSPHERE EQUIPMENT FOR RESISTOR FURNACES. Many of the applications of heating of metal parts require a protective atmosphere in the furnace heating and cooling chambers to protect the surface of the parts being treated. Practically all these applications require the prevention of the oxidation of the metal. In addition there may be other requirements such as preventing the removal of carbon, the elimination of sulfur discoloration, or the addition of carbon.

Typical applications requiring a protective atmosphere are bright-annealing of copper and steel, scale-free hardening, scale-free annealing of castings, electric furnace brazing, sintering, etc. A suitable protective atmosphere is provided by equipment which processes the available gas, such as city gas, natural gas, and propane.

Standard atmosphere equipments are available for providing the proper atmosphere for the many metal-treating processes.

One type of standard equipment consists of visual flowmeters to indicate the amount of air and gas used, a motor-driven air-gas mixer and compressor, a combustion chamber with burner, and a surface cooler for removing excess moisture. In operation, air and gas are fed into the combustion chamber at a definite ratio, which depends on the gas used and the required analysis of the output gas. In the combustion chamber, the gas is burned with a deficiency of air in the presence of a catalyst under controlled conditions. The output gas contains principally nitrogen, hydrogen, carbon monoxide, carbon dioxide, and water vapor. The relative proportions of the constituent gases depend on the original air-gas ratio. The resultant atmosphere is suitable for many of the furnace applications.

For some applications, the output gas must be further purified. For example, most city gases contain a small amount of sulfur which must be removed if material such as copper and nickel are to be bright annealed. In other applications, such as annealing or heat-treating of high-carbon steel, the carbon dioxide and water vapor must be removed to provide a nondecarburizing atmosphere. Standard equipments are available to provide such purification of the gases.

The cost of a protective atmosphere is relatively low. For instance, in bright-annealing of copper with available city gas of 530 Btu content per cu ft, the air-gas ratio used is approximately 4 : 1. Therefore, a gas output of 1000 cu ft would require approximately 250 cu ft of city gas. For scale-free hardening, the air-gas ratio may be approximately $2\,^1/_2$: 1, and there would be required approximately 400 cu ft of city gas of 530 Btu per 1000 cu ft of output gas.

When a higher reducing gas than that provided by processing available gases is desired, an ammonia dissociator may be used. The equipment is essentially a tube or coil containing a catalyst through which the ammonia gas passes, inserted in an electric furnace. The ammonia gas dissociates when heated to the required temperature, the resulting gas containing 75% hydrogen and 25% nitrogen. Many sizes of standard atmosphere equipments are available for a wide range of outputs and applications. Makers should be consulted in regard to equipment for special conditions.

The quantity of atmosphere required depends on the type and size of furnace, and the application. In general, it is a relatively small item in the total cost. Such protective atmosphere easily can be supplied to practically all types of furnaces, if they are properly designed for use with protective atmosphere.

The protective atmosphere eliminates oxidation of most materials. A considerable saving is effected thereby, by the elimination of the subsequent cleaning operation, and the quality and appearance of the product is improved. The cost of fabrication, such as brazing fabricated metal parts in the electric furnace, is lowered.

SELECTION OF TYPE. ENERGY REQUIRED. Table 1 gives, in general, the types of furnaces used for various applications. The type and size of furnace to be selected depend on the size, shape, weight, and material of parts to be treated, as well as the production and the desired heating and cooling cycle. The energy required, usually stated in net pounds per kilowatthour, based on continuous operation, depends on the size of furnace, production, and the heating cycle. The data in Table 1 are approximate and are to be used only as a rough guide.

ENERGY CONSUMPTION AND ELECTRICAL RATING. An estimate of the energy required for a given application should include the heat absorption of the materials being heated, heat absorption of auxiliaries for carrying the work, as trays, conveyor,

Table 1. Typical Applications of Electric Resistance Furnaces

Process	Material	Type of Furnace	Typical Applications	Approx. Energy Required, lb/kwhr
Annealing	Copper and brass	Box Pusher tray Conveyor Roller hearth Bell	Copper wire on reels Copper tubing Brass wire or strip in coils	25–35 12–20 15–20
	Malleable iron	Elevator Pusher tray Roller hearth	Malleable castings	5–7
	Steel bar Stock and tubes	Car bottom Pit Elevator Roller hearth		6–8 7–10 6–8 7–11
	Steel sheets Coiled strip	Bell Elevator	Steel strip in coils	11–14
	Steel strip, continuous	Roller hearth Catenary Tower		8–12
	Steel wire in coils	Bell		10–13
	Steel castings and forgings	Car bottom Elevator Pusher tray Roller hearth		7–10
	Stainless steels	Mesh belt Roller hearth Catenary Tower		4–7 6–10 6–10 6–10
Annealing Heat-treating	Aluminum Aluminum alloys	Box Pit Elevator Roller hearth Salt Baths		Aluminum 8–14 Aluminum alloys 6–12
Brazing (copper-brass and silver solder)	Steel Copper Aluminum	Box Mesh belt Roller hearth		For copper brazing 4–6 3–5 5–7
Carburizing	Steel	Box Elevator Pusher tray Pit	Pack method Gas carburizing	2–4 3–6
Drawing	Steel	Box Pit Oil bath Salt bath Conveyor	At approx. 400 F At approx. 800 F At approx. 1200 F	40–60 20–25 10–15
Galvanizing	Steel	Pot	Hot-dip galvanizing	12–20
Hardening	Steel	Box Pot Pit Conveyor Pusher Rotary hearth Roller hearth	At approx. 1500 F	7–11
Porcelain enameling	Steel Cast-iron	Box Continuous-conveyor	Sheet steel, single coat In box furnace In continuous furnace Cast iron, wet process, single coat In box furnace In continuous furnace	5–8 10–15 6–10 12–15
Sintering	Pressed metal powders	Bell Box Conveyor Roller hearth		

etc., heat absorption of the ventilating air if used, heat absorption of the protective gas atmosphere if used, heat losses through the walls, doors, etc.

The heat absorption of the material to be heated, including the net work, conveyor, trays, etc., can be calculated by

$$\text{Kilowatthours} = \frac{w \times h_s \times (t_2 - t_1)}{3412}$$

where w = weight of material being heated, h_s = average specific heat, t_1 and t_2 = respectively, initial and final temperatures of the material in degrees Fahrenheit. Heat losses for many applications may be estimated by means of Figs. 7-11. The heat loss data in the series of curves are principally for low-temperature applications. For the higher-temperature resistance-type furnaces, operating up to approximately 1850 F, a good rule-of-thumb method for estimating the heat loss in kilowatthours is

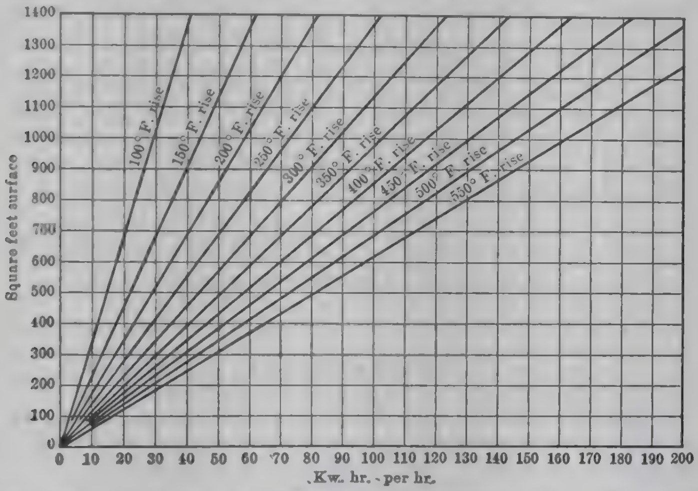

FIG. 7. Heat loss through 1-in. thick insulation of 85% magnesia or similar insulator. Heat loss varies inversely as thickness.

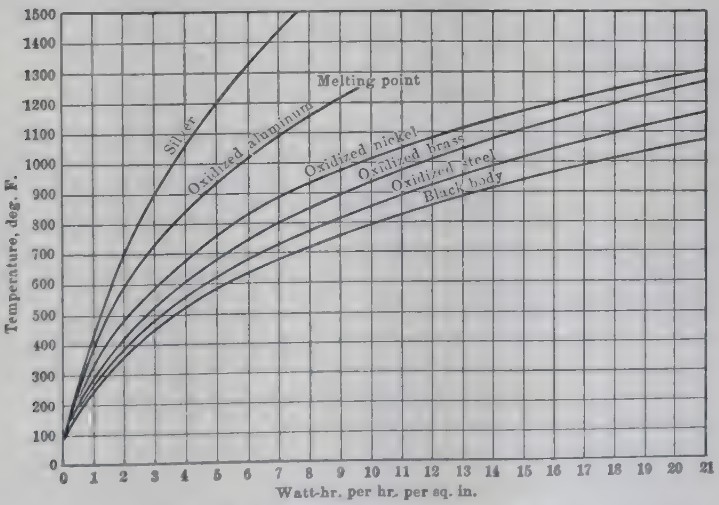

FIG. 8. Heat losses from various metals.

$$\text{Kilowatthours} = \frac{0.8A \times T}{10{,}000}$$

where A = inside wall area of heating chamber in square feet and T = operating temperature in degrees Fahrenheit. The application of this rule will give the approximate heat losses through the insulated walls and closed doors, based on a well-insulated furnace.

The selection of the right type and size of furnace for a given application requires experience and, in some cases, tests. When there is any question as to size and type of furnace, manufacturers of such equipment should be consulted. Complete data should be given, i.e., voltage, phase, and frequency of the power circuit; floor space and headroom available; the size, shape, weight, and material of parts to be treated; the complete heating and cooling cycle desired; the efficiency of loading, i.e., pounds of material to be loaded per square foot or cubic foot; production per given time; and hours to be operated per day.

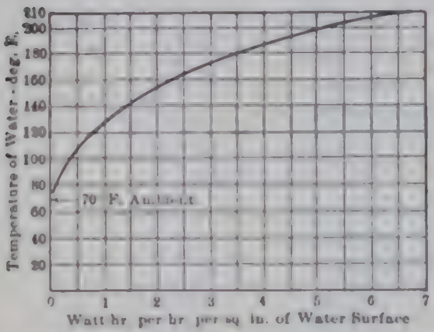

FIG. 9. Heat losses from open water surfaces.

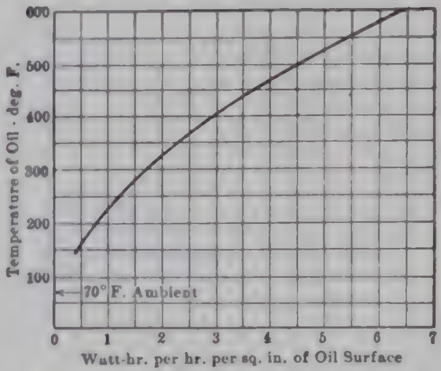

FIG. 10. Heat losses from surfaces of oil baths.

REFRACTORIES AND INSULATION FOR OVENS AND RESISTOR FURNACES. The usual construction of ovens, for temperatures up to approximately 600 F, comprises a metal inner liner and an outer shell, the space between being filled with insulating material, as 85% magnesia, rock wool, mineral wool, etc., care being used to have little or no through metal.

The thickness of insulation used depends on the operating temperature and, in general, should be at least as follows:

Oven temperature, °F	200	400	600	800
Approximate thickness of insulation, in.	2	4	5	6

For electric-resistance furnaces, the wall construction consists of an inner refractory lining of brick, backed by a suitable thickness of insulating material. Several types of lightweight refractory are available in standard brick sizes. These bricks are of less than half the weight of regular firebrick, thereby providing for additional insulation and absorbing less heat while the furnace is being heated to operating temperature. For the average-size heating chamber, the inner refractory lining of 4 1/2-in. standard lightweight refractory brick is sufficient. For high walls and long spans for arches, this thickness should be increased. For data on refractory brick see pp. 5-46 to 5-56 of this book. For additional data on heat insulation see *Power* Volume of Kent's *Mechanical Engineers' Handbook*, pp. 3-34 to 3-49.

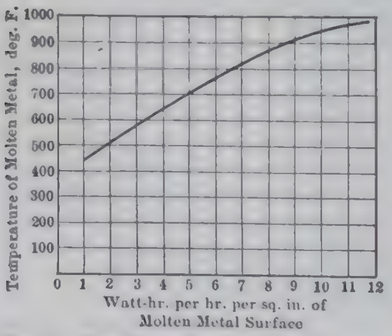

FIG. 11. Heat losses from surface of molten lead, tin, type metal, babbitt, etc.

The thickness of insulation depends on the operating temperature and the complete time-temperature cycle. A furnace to be held at operating temperature for long periods should be well insulated. For a cycle requiring cooling of the charge in the furnace, the thickness of the insulation must be in accordance with the required heating and cooling cycle.

In furnaces held at the operating temperature, the thickness of the insulation, in addition to the refractory lining, should be approximately as follows:

Operating temperature, °F	800–1100	1100–1400	1400–1800	1800–2100
Approximate thickness of insulation, in.	5	7 1/2	10	12 1/2

9. MELTING FURNACES

The three types of electric melting furnaces are, in general, the resistance furnace, the arc furnace, and the induction furnace.

RESISTANCE FURNACES, usually of the pot type, are used for melting soft metals, as tin, babbitt, lead, solder, type metal, etc. The heating units may be immersed directly in the metal to be melted or placed outside of the melting crucible, depending on the application.

ARC FURNACES, in general, are of two types, the direct arc and the indirect arc. **The direct arc furnace** is used principally for melting and refining steel. The three-phase arc furnace, generally used, has three electrodes. The electric current passes between the electrodes and the bath of metal. Each electrode is provided with a motor-driven mechanism which, by suitable automatic control, raises and lowers the electrodes to maintain a constant power input.

The indirect arc furnace usually has two electrodes. The current passes between the electrodes and above the bath, which is heated by radiant heat from the electric arc, as well as by conduction and convection. This type of furnace is used frequently for melting of copper and brass.

Electrical equipment of an electric arc furnace consists of a stepdown transformer, primary and secondary control, motors for raising and lowering the electrodes, and a tilting motor if the furnace is to be of the tilting type. The primary control consists of an oil circuit breaker on the high-voltage side of the stepdown transformer, suitable means for changing taps on the transformer, and metering equipment. The secondary control consists of control equipment for controlling the movement of the electrodes to maintain constant power input. Voltages used on the arc vary, depending on the character of the application. The higher voltages are used normally for melting down, and the lower voltages for refining.

INDUCTION FURNACES are of two types, the core type, used on standard frequencies, and the coreless or high-frequency furnace.

Core-type furnaces consist essentially of an electrical transformer circuit with a primary coil, a laminated iron core, and the bath arranged for completion of the secondary circuit. Heating is accomplished by the induced current in the secondary. This type of induction furnace is used principally for melting brass and copper.

Coreless or high-frequency furnaces consist of a crucible to hold the material to be melted, around which is placed a water-cooled copper coil to which the high-frequency source is connected. Heat is generated by the electric current induced in the charge. The rate of heating is limited practically only by the capacity of the high-frequency source. This type of furnace provides for rapid heating, accurate control of heating, and agitation of the bath, and is used principally for the melting of alloy steel.

ENERGY REQUIRED FOR MELTING in induction furnaces depends on the size of furnace and the material to be melted. In general, the approximate electric energy consumption for melting for various applications is as follows:

Brass, yellow (core induction furnace)	220–350 kwhr per ton (2000 lb)
Brass, red (core induction furnace)	250–400 kwhr per ton (2000 lb)
Copper (indirect arc furnace)	250–400 kwhr per ton (2000 lb)
Steel (three-phase arc furnace melting only)	450–600 kwhr per ton (2000 lb)
Steel (coreless induction furnace)	500–800 kwhr per ton (2000 lb)

10. INDUCTION HEATING

Induction heating has been widely applied for the hardening of steel parts and for heating for forging.

The physical requirements for induction heating are not complicated. Besides the metal parts to be heated, the heating coil or inductor block and a source of alternating current are required. The high-frequency current passing through the heating coil produces a fluctuating magnetic field. This in turn induces a current to flow in the metal part, with resultant heating due to the I^2R loss in the portion of the metal in which the current flows.

The advancement of induction heating is closely related to the development of electrical equipment for converting 60-cycle frequencies to the higher frequencies required. Today, three types of commercial equipments covering a wide range of power output and frequency ratings are available. The three sources of high-frequency power (high frequency covering a range of 1000 to 1,000,000,000 cps) are:

1. Motor generators, for frequencies 1000, 3000, or 10,000 cps and output ratings up to 1200 kw.
2. Spark-gap oscillators, providing frequencies of 100 to 400 kc per second at power output ratings up to 25 kw.
3. Vacuum-tube oscillators, providing alternating current with frequencies of 100 to 500 kc, and power output rating in the lower range of frequencies up to 200 kw.

All three types of equipment are in general use. Suitability of each for any particular job depends on several factors, including size of part, power requirement, metallurgical results desired, and relative cost.

Induction heating is particularly suited for surface-hardening or localized hardening of steel parts.

An example of surface-hardening of a part is illustrated in Fig. 12, which shows the induction-hardening fixture for surface-hardening of a cluster gear. The gear is placed on a holding device which slowly rotates it inside the heating coil which is connected to the source of high frequency. Control of the heating is by automatic timing. After the proper temperature is reached, the high-frequency power is shut off and the gear is quenched by a water spray issuing from the numerous small holes in the surrounding jacket.

For the heating of large parts for forging, such as 3-in. diameter round solid bars, where it is desired to heat all the way through, a frequency of 1000 or 3000 cps is usually employed. Where it is desired to surface-harden the wearing surface of a fairly heavy part such as a crankshaft, a frequency of 3000 or 10,000 cps is used. For the heating of small parts or irregularly shaped parts, and where shallow depth of heating is desired, frequencies up to approximately 500 kc are used.

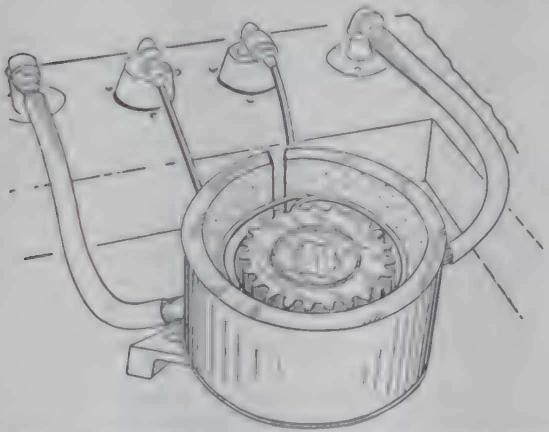

FIG. 12. Gear being heated in induction-hardening fixture.

In addition, high frequency is used for annealing, brazing, and soldering operations where localized heating is desired.

Normally, the high-frequency equipment is provided with coils, fixtures, and conveyors designed to handle the particular part.

Some outstanding and typical examples of the use of high frequency for surface hardening are: bearing surfaces of crankshafts, cam shafts, cutting edges of mowing-machine sections, wearing surfaces of the ways of lathe beds, wearing surfaces of gears, and cutting edges of pliers, axes, and hatchets.

Some of the outstanding advantages in the use of high frequency in heating for forging are: improved working conditions, quick heating, less oxidation of the steel (giving longer die life), less loss of metal, and better control for forging temperature.

Other excellent applications of induction heating using frequencies obtained from motor-generator equipment are the heating of steel strip continuously for annealing and the reheating of tinplate strip for tin reflowing.

11. HEATING OF ELECTRICAL NONCONDUCTORS

Parts to be heated are placed between plate electrodes to which the high-frequency voltage is supplied. The heating is the result of dielectric loss within the material.

For the heating of these electrical nonconductors, frequencies of 3 to 100 megacycles are normally used, depending on the material to be heated.

Some of the typical examples of commercial applications in use are: heating of plywood and other laminated wood structures for bonding; preheating of plastic preforms prior to molding; heating for controlled drying, as in heating paper, textiles, etc.

It must be kept in mind that dielectric heating equipment is not economical for mass heating or for evaporation of large quantities of water where other forms of heating can be successfully applied.

One of the outstanding applications of dielectric heating has been the heating of plastic preforms before molding. With dielectric preheating, the heat is generated within the preforms by the high-frequency electric field. A uniform temperature distribution is obtained throughout the charge. The older method of preheating depended on conduction, convection, or radiation. The heating was slow, and the high temperature on the outside of the part initiated a chemical reaction while the interior temperature was still low. The benefits obtained from a uniform, quick heating by dielectric preheating are: improved quality and reduction of scrap; reduction of mold repairs; increased production from a given mold; reduced cost of finishing molded parts, because of thinner flash on the mold parting line; increased range of designs which can be molded.

Figure 13 shows a typical dielectric heater for plastic preforms, rating 5 kw output at 40 megacycles.

Where it is desired to obtain a uniformity of drying or a greater degree of drying than is possible or practical with any other method of heating, dielectric heating may be applicable. The equipment may be provided with conveyorized ovens that provide for passing the material to be dried between electrodes in the oven.

When dielectric heating is being considered, the problems should be referred to the manufacturer of such equipment. Tests on the product are frequently required to determine the practicability of the heating of the particular material and the frequency required.

SINGLE-POINT METAL-CUTTING TOOLS

By Robert C. Deale

1. DEFINITIONS

The following definitions for the various elements of a single-point metal-cutting tool, which have been adopted for general use in the United States, are covered by Standard B5.13-1939, Terminology and Definitions for Single-point Cutting Tools, of the American Standards Association.

COMPONENTS. **The shank** is that part of the tool on one end of which the point is formed or the tip or bit supported.

The size of a tool of square or rectangular section is expressed by giving in the order named the width of shank, the height of shank, and the total tool length in inches, i.e., $^3/_4$ by 1 $^1/_2$ by 12 in.

The point or nose is all that part of a tool which is shaped to produce the cutting edges and face. (See Figs. 1 and 2.)

The neck is an extension of the shank but of reduced sectional area. (See Fig. 3.)

Ordinary Tipped Tool

FIG. 4. Tipped tools.

The base is that side of the shank which bears against the support taking the tangential pressure of the cut.

The face is that surface on which the chip impinges as it is cut from the work.

The heel is the end of the base immediately below and supporting the face.

The cutting edge, or lip, is that portion of the face edge along which the chip is separated from the work. It consists usually of the side cutting edge, the nose radius, and the end cutting edge. (See Fig. 1.)

The nose is the curve formed by joining the side and end cutting edges.

The profile is a plan view when looking at the face from a point at right angles to the base. It is formed by joining the side and end cutting edges with the nose.

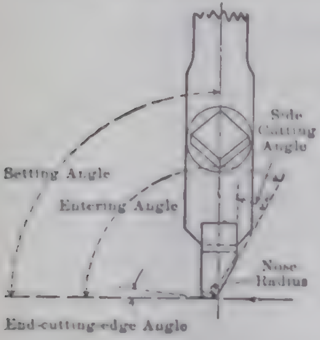
The flat is a straight portion of the cutting edge intended to produce a smooth machined surface.

The flank of the tool is the surface below the cutting edge.

TYPES OF TOOLS. Single-point tools may be made up as follows:

A ground tool is one in which a point is formed on the end of a bar (shank) of tool steel by grinding. (See Fig. 1.)

A forged tool is one in which the point is forged roughly to shape on the end of a bar (shank) of tool steel and subsequently hardened and ground. (See Fig. 2.)



A tipped tool is one with a tip of cutting material permanently attached to a shank of noncutting metal. (See Fig. 4.)

A bit tool is one in which a small part of tool material of square, rectangular, or other section, or forged to a special shape, is held in the end of a holder or shank. (See Fig. 5.)

A tool bit is a relatively small piece of tool material clamped in a tool holder in such a way that it can be readily removed and replaced.

A right-cut single-point tool is one in which the cutting edge is on the right side when looking at the point end of the tool with the face upward and the shank pointing away.

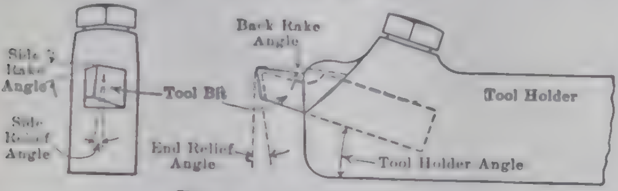


Fig. 5. Tool bit and holder.

A left-cut single-point tool is one in which the cutting edge is on the left side when looking at the point end with the face upward and the shank pointing away.

An end cut tool is one having its principal cutting edge on the end.

A straight tool is one in which the point is on the forward edge of a straight shank. (See Fig. 1.)

A bent tool is one in which the point is bent to the right or the left. A right bent tool has the point bent to the right when looking at the tool from the point end with the face upward and the shank pointing away. (See Fig. 6.)

The shank angle is the angle by which the point of a bent tool deviates from the straight portion of the shank. (See Fig. 6.)

An offset tool is one in which the point is at either side of, but parallel to, the shank. In a right offset tool, the point is offset to the right of the shank when looking at the tool from the point end with the face upward and with the shank pointing away. (See Fig. 7.)

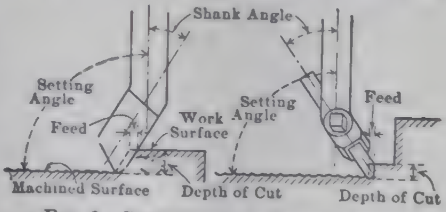

Fig. 6. Bent-shank, single-point tool.

TOOL ANGLES. The angles defined below are angles formed between various portions or surfaces of the tool. They are angles formed in forging or grinding the tool, and should not be confused with the working angles which mainly are angles formed between some surface of the tool and of the work.

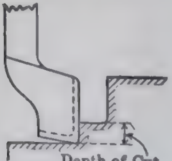

Fig. 7. Right-cut, right-offset, single-point tool.

Back-rake angle is the angle between the face of a tool and the shank base, measured in a plane at right angles to the base and parallel to the center line of the nose. The angle is positive if the face slopes downward from the nose toward the shank, and negative if the face slopes upward toward the shank.

Side-rake angle is the angle between the face of the tool and the shank base, measured in a plane at right angles to the base and at right angles to the center line of the nose.

Relief angle is the angle between a plane perpendicular to the base of a tool or tool holder and that portion of the flank immediately adjacent to the cutting edge.

Side relief angle is measured in the plane of the side-rake angle to the center line of the tool nose.

The end relief angle is measured in the plane of the back-rake angle.

The clearance angle is an angle between a perpendicular to the base of a tool and that portion of the flank immediately adjacent to the base. The side clearance is measured in the plane of the side-rake angle. The end clearance is measured in the plane of the back-rake angle.

The side-cutting-edge angle is the angle between the straight cutting edge on the side of the tool and the side of the tool shank.

The end-cutting-edge angle is the angle between the cutting edge on the end of the tool and a line at right angles to the side edge of the tool shank.

Nose angle is the angle included between the side cutting edge and the end cutting edge. (See Fig. 1.)

WORKING ANGLES are those angles between the tool and work which depend not only on the shape of the tool but also on its position with respect to the work.

Setting angle is the angle made by the shank of a tool with a line at right angles to the finished surface of the work. (See Figs. 5 and 6.)

The entering angle is the angle which the side cutting edge of the tool makes with the finished surface of the work. (See Fig. 5.)

True rake angle (or top rake) is the actual slope of the tool face from the active cutting edge in the direction of chip flow. It is a combination of front and side-rake angles and varies with the setting of the tool and with the feed and depth of cut.

Lip angle is the included angle of the tool material between the face and the ground flank, measured in a plane at right angles to the cutting edge. When measured in a plane perpendicular to the cutting edge at the end of the tool it is called the end lip angle. When measured in the direction of chip flow, it is called the true lip angle. (See Fig. 8.)

The working relief angle is the angle between the ground flank of the tool and a line, tangent to the cut surface, passing through the active cutting edge.

Cutting angle is equal to the lip angle plus the working relief angle at the point of action.

The working end-cutting-edge angle is the angle between the straight end cutting edge and a plane tangent to the machined surface at the point of cutting.

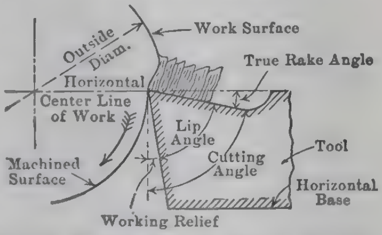

FIG. 8. Section through plane of chip flow, indicated as *AA* in Figs. 1 and 2.

CUTTING SPEED is the peripheral or surface speed of the work with respect to the tool. In turning, it usually is measured on the uncut or work surface of the work ahead of the tool.

DEPTH OF CUT is the distance between the bottom of the cut and the uncut surface, measured in a direction at right angles to the finished surface of the work.

FEED is the relative amount of motion of the tool into the work for each revolution, stroke, or unit of time.

MACHINED SURFACE is the surface left by the cutting tool. (See Figs. 6 and 8.)

WORK SURFACE is the surface that is to be machined. (See Figs. 6 and 8.)

2. TOOL CONTOUR AND SIZE

For complete data on the use of cutting tools, including feed and speed data for many varieties of alloy steel, see Ref. 1.

CHIP PROPORTIONS. The proportions of a chip, as affected by the nose contour of a tool or by the relation between depth of cut and feed, have great effect on the cutting speed which may be used. A change in chip proportions caused by a change in nose contour of the tool has the same effect on cutting speed as a similar change caused by a change in depth of cut and feed. When removing a chip of given cross-sectional area, changes in the tool contour may cause variations in the cutting speed of as much as 60%, while changes of as much as 400% may be caused by changes in the relation between depth of cut and feed.

TOOL SIZES. The number of sizes of tools used in a given shop should be as small as possible. The following sizes should meet all ordinary shop requirements: *Rectangular Tools:* $^3/_8$ by $^3/_4$ in.; $^1/_2$ by 1 in.; $^5/_8$ by 1 $^1/_4$ in.; $^3/_4$ by 1 $^1/_2$ in.; 1 by 2 in.; 1 $^1/_2$ by 3 in. *Square Tool Bits:* $^3/_{16}$, $^1/_4$, $^3/_8$, $^1/_2$, $^5/_8$, $^3/_4$, 1, 1 $^1/_4$, and 1 $^1/_2$ in. *Rectangular Tool Bits:* $^3/_{32}$ by $^1/_2$ in.; $^1/_8$ by $^3/_4$ in.; $^3/_{16}$ by 1 $^1/_8$ in.; $^1/_4$ by 1 $^3/_8$ in. A relatively small number of the foregoing sizes should be ample for all except the largest machine shops.

Tool bits forged to the desired form are available. Such bits must be used in special holders, usually made by the company furnishing the bits. Such bits are at times very convenient for shop use, but are much more expensive per pound than bar stock. When such tools and holders are adopted, both the stiffness of support to the cutting edge and the percentage of the new tool which may be used before it is discarded should be considered.

Effect of Tool Size. The size of a tool has no effect other than to give strength to the tool, to reduce deflection, or to increase the tool width available for a forming cut. A properly supported small tool may be run at the same cutting speed as a large one having the same shape, for the same depth of cut and feed. Lack of rigidity of a tool tends to increase the possibility of chatter.

TOOL FORM. When heavy roughing cuts are to be taken, and it is desired to use heavy forged tools, there are no better shapes of tool than those developed by Carl Barth. They are shown in Fig. 9. Dimensions are given in Table 1.

Table 1. Dimensions of Round-nose Forged Single-point Tools

(Left-cut straight tool with raised face. Barth standardization. See Fig. 9.)

Tool size, in., *W*	1/2	5/8	3/4	7/8	1	1 1/4	1 1/2	1 3/4	2

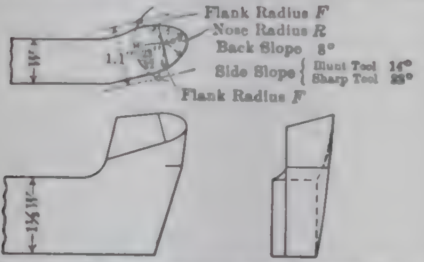

FIG. 9. Left-cut, straight-shank, round-nose tool with raised face.

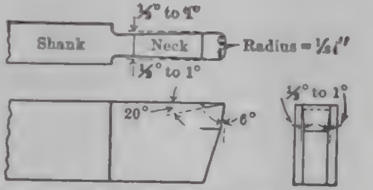

FIG. 10. Recommended shape of parting tool.

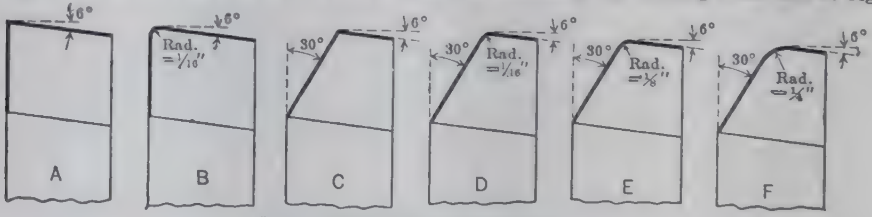
Tools of the form shown in Fig. 10 are used for parting cuts. They usually are 1/2 to 5/8 in. wide at the nose, except when the diameter of work to be parted is large, when they may be wider. To obtain the necessary stiffness, the cutting section of such a tool usually is forged down from a shank of comparatively large section. Note that the sides of the neck of this parting tool converge at a slight angle, usually 1/2 degree to 2 degrees, to avoid interference with the side of the cut. The side relief angle is small, usually not over 2 degrees. At times a blade having a height of five to eight times its width, held in a special holder, is used as a parting tool.

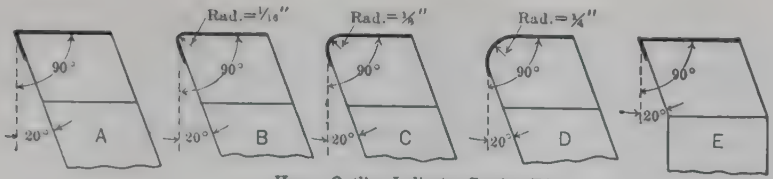
The contours shown in Fig. 11 are suitable and recommended for right-cut tool bits, or small solid tools ground directly from the bar. A similar set of tools, with the cutting edge on the right-hand side of the tool, would be necessary for cutting from left to right.



Heavy Outline Indicates Cutting Edge

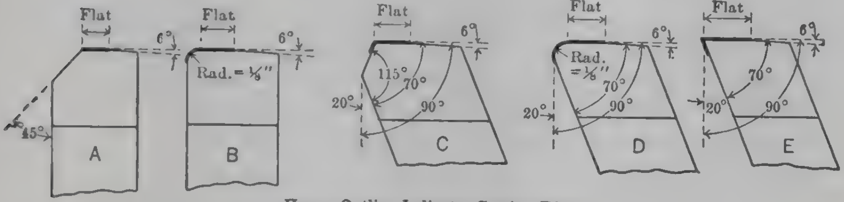
FIG. 11. Recommended contour, right-cut roughing tool.

For facing operations the active cutting edge is on the end of the tool, preferably with a back rake equal to the side rake used on ordinary roughing tools, and with a side slope of approximately 8 degrees. The right-cut contours shown in Fig. 12 should be ample for all ordinary operations. A similar set, with the active cutting edge on the opposite side of the tool, would be required for left-cut tools.



Heavy Outline Indicates Cutting Edge

FIG. 12. Recommended contour, right-cut facing tool.



Heavy Outline Indicates Cutting Edge

FIG. 13. Recommended contour, right-cut finishing tool.

Table 2. Rake and Relief Angles for High-speed Steel Tools Cutting Various Metals

	Finishing	8	16–22	0	5–9
	Parting	6–12	0	1/2–2	5–9
	Forming	12–20	0	0	3–5
Magnesium alloys	Roughing	5–8	3–5	6–10	6–10
	Finishing	10–15	0	0	6–10
	Parting	10–15	0	6–10	6–10
	Forming	5–10	0	0	6–10

Tools for finishing cuts should have an appreciable flat on the end, substantially wider than the feed per revolution or stroke. (See Fig. 13.)

RAKE ANGLE. There seems to be little necessity for making any considerable variation in rake and relief. While cutting pressures are decreased by an increase in rake, the cutting speed is not greatly affected by such changes. While the chip is removed with less expenditure of energy by the tool having the greater rake, the reduction in cutting angle tends to weaken the tool, and so causes failure sooner than would be the case if a smaller rake were used.

The values of rake given in Table 2 are based on the practice of a leading manufacturing company, for use with high-speed steel tools. For cutting ingot iron the following tool angles are recommended by a leading producer: back rake 15 degrees; side rake 28 to 32 degrees, front and side clearance 8 to 10 degrees; side and end cutting edge each 15 degrees, and tip radius $\frac{1}{32}$ to $\frac{1}{16}$ in. For cutoff tools back rake should be 20 to 30 degrees, front clearance 8 to 10 degrees, and side clearance 2 degrees.

Table 3 shows the practice recommended for use with cemented carbide tools.

Table 3. Rake and Relief Angles for Cemented Carbide Tools Cutting Various Materials

Material to Be Cut	Rake, degrees		Relief, degrees	
	Side	Back	Front	Side

3. CUTTING SPEEDS AND FEEDS

ECONOMIC TOOL LIFE. Under a given set of conditions, it may be shown that there is a particular tool life which gives lowest overall costs. This tool life, and the accompanying cutting speed, may be calculated if all data are available. The values given in Table 4, however, may be used without great loss in efficiency.

Table 4. Economic Tool Life under Cut

(High-speed steel tools, cutting steel, and cast iron)

Machine	Tool Setting	Economic Tool Life, min
Engine lathe or planer	Ordinary	40
	Accurate	120
Drill press	Ordinary	30
Hand screw machine	Ordinary	120
Automatic screw machine	Ordinary	400
Automatic milling machine, simple cutters	....	600
Milling machine, ordinary cutters	....	250
Milling machine, large forming cutters	....	2000

Speeds and feeds for cemented carbides are given in Table 26. In general, feeds are approximately the same as those used with high-speed steel tools, up to a maximum of approximately 0.063 in. per revolution, with speeds five to six times those used with high-speed steel tools. Tool life under cut should be at least 60 min.

Table 5 shows the effect of variations in cutting speed on tool life. This table is based on a value of unity for a tool life of 60 min. If the proper cutting speed is known for a cut A of given duration, the speed for a cut B of different duration may be obtained by the formula

Table 5. Effect on Tool Life of Variations in Cutting Speed

Tool Life, min	Carbon Steel Tools			High-speed Steel Tools						Stellite Tools			Cemented Carbide Tools

$$S_b = S_a \times \frac{F_b}{F_a}$$

where S_b, S_a = respectively cutting speeds of A and B, and F_a, F_b = respectively tool life factors for A and B from Table 5.

Example. A cutting speed of 95 ft per min in rough turning steel with high-speed steel tools gives a tool life of 45 min. Required the cutting speed to give a tool life of 120 min.

Solution. $A = 45$; $B = 120$; $S_a = 95$. From Table 5, tool life factor $F_a = 1.04$, and $F_b = 0.92$. Then $S_b = 95 \times (0.92/1.04) = 84$ ft per min.

ECONOMIC PRODUCTION. To keep costs at a minimum in rough machining operations, the maximum volume of chips per minute must be removed. This involves: (1) The maximum depth of cut that can be taken without distortion of the part machined, up to the point where all surplus stock is removed in a single roughing cut. (2) A relatively large feed, which gives thick chips, preferably above 0.030 in. (3) The use of a tool having a contour which gives the smallest possible chip thickness for a given feed without setting up injurious chatter. Increase in the nose radius or the side-cutting-edge angle decreases chip thickness under constant conditions of feed and depth of cut. (4) A cutting speed such that the life of the tool approximates the economic life.

It must be realized that the power available for driving the machine tool may limit the rate of stock removal.

MATERIALS CUT. Tables 6, 7, and 9 give the approximate relative machinability, based on the speed with which a given cut may be taken, of a large number of common materials. These tables may be used to determine the correct cutting speed and horsepower requirements for the various materials under a variety of working conditions, by use of the multipliers for speed and horsepower in connection with the basic data given in Tables 10 to 17. Table 6 is based on C1030 hot-rolled steel (see Tables 10 to 13) and Table 7 is based on cast iron of 177 Brinell hardness and tensile strength of 30,000 psi (see Tables 14 to 17).

Example. Required the correct cutting speed and the horsepower for turning 2330 steel, normalized, using a round-nose tool set at an angle of 30 degrees to the work, with a 1/8 in. depth of cut and a 1/32 in. feed.

Solution. From Table 12, the desirable cutting speed for C1030 hot-rolled steel, under the conditions given, is 80 ft per min. The horsepower required at the nose of the tool is 2.5. From Table 6, the multiplier for speed for 2330 normalized steel is 0.68 and the multiplier for horsepower is 0.65. Cutting speed for 2330 normalized steel equals 80 × 0.68 = 54.4 ft per min. Horsepower required at nose of tool = 2.5 × 0.65 = 1.63.

(Continued on p. 23-13)

Table 6. Machinability Constants of Steel

(For analysis of the various steels listed, see pp. 2-25 to 2-28.)

Steel, AISI No.	Condition*	Heat Treatment			Physical Properties					Chip Pressure Constant, K_1	Multipliers for C1030 HR Values (See Tables 10 to 13)		Relative Machinability
		Heat to, °F	Quench in	Draw at, °F	Tensile Strength, psi	Yield Point, psi	Elong. in 2 in., %	Reduction of Area, %	Brinell Hardness No.		Speed	Hp

TOOL PRESSURE. F. W. Taylor (Ref. 2) found that no definite relation exists between the cutting speed of tools and the pressure, tangential to the finished surface of the work, exerted on the tool by the chip.

The value of this tangential component, which is of interest in the design of machine tools, is

$$P = K_1 L^{1.1} T^{0.78}, \text{ for cutting steel}$$

and

$$P = K_2 L T^{0.66}, \text{ for cutting cast iron}$$

where K_1, K_2 = constants, given in Tables 6 and 7; L = total width of chip, inches, which for the average tool is equal to the total length of cutting edge of the tool in contact with the work (see Fig. 14); T = average thickness of the chip, inches. This usually equals (Feed × Depth)/L. (See Ref. 1, Chap. 22.)

METAL CUTTING TESTS, to be on a thoroughly scientific basis, require the consumption of much more time and material than usually are available in the average shop. Standard B5.19-1946, of the American Standards Association, outlines a procedure for the making of such tests. For further discussion of the subject, see Refs. 1, 3, 4, and 5.

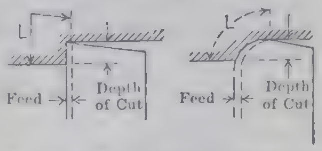

Fig. 14. Determination of factor *L* in formula for tool pressure.

CUTTING SPEED TABLES. Table 10 gives cutting speeds and horsepower at the point of the tool for cutting C1030 hot-rolled steel with high-carbon steel tools, and Table 14 gives corresponding data for cutting a medium cast iron with carbon steel tools.

Tables 11, 12, and 13 give cutting speeds and net horsepower at the point of the tool for cutting C1030 hot-rolled steel with high-speed steel tools of 18-4-1, 14-4-2, or molybdenum tungsten grades. Tables 15, 16, and 17 give corresponding data for cutting a medium cast iron (177 Brinell) with high-speed steel tools.

These tables are based on a 60-min tool life. To obtain cutting speeds that permit obtaining some other tool life, multiply the speeds given in the speed and feed tables by the factor corresponding to the desired tool life, as obtained from Table 5.

The horsepower given is that developed at the nose of the tool and does not include any losses in the machine tool. To allow for the efficiency of the average machine tool, it is necessary to increase the powers given in the tables by approximately 50% to obtain the power input to the machine required to drive a particular cut. In addition, there is an idle load, ranging from one-half to 5 horsepower which must be added to the gross horsepower obtained above to secure the required motor input.

Table 7. Machinability Constants of Cast Iron

Chemical Composition				Physical Properties			Chip Pressure Constant, Kg	Multipliers for Cast Iron of 177 Brinell (See Tables 14 to 17)		Relative Machinability

MONEL METAL. Table 8, giving cutting speeds for Monel metal, with high-speed steel tools, is based on experiments by the International Nickel Company, and by Melvin Matson at Montana State College. Speeds given should permit securing a tool life of 60 min between grinds.

Tools for turning **Monel metal** should be of much the same shape as those used for turning medium steel. Because of the toughness of the chip it is particularly desirable to use a chip breaker.

(Continued on p. 23-18)

Table 9. Relative Machinability of Nonferrous Metals

(Based on cutting speed)

ALUMINUM. Information on cutting tools, speeds, and feeds for aluminum and its alloys is found in Section 4, Article 6.

MAGNESIUM. Details concerning machining practices and cutting tools for magnesium and its alloys are given in Section 4, Article 14.

INGOT IRON. For maximum metal removal and best finish, relatively fine feeds and deep cuts should be used with ingot iron and other ductile, low-carbon ferrous materials.

4. CUTTING FLUIDS

The various fluids used in metal-cutting operations serve these purposes: (1) Cooling the tool. (2) Cooling the work. (3) Improving the quality of the surface produced. (4) Lubricating the surfaces in contact between the tool and work, or preventing welding of chip or work to the tool, thus aiding in reducing the temperature of the tool. (5) Flushing away the chips. (6) Reducing the pressure of the chip on the tool.

For cooling tool and work and flushing away chips, the quantity of fluid is more important than the kind. A thin soluble oil solution, approximately 40-1, or a solution of soda or borax in water is very satisfactory. A pure oil or a rich mixture of soluble oil does not appear to be so efficient a coolant as a fluid which is mainly water.

An oil containing a large percentage of sulfur appears to reduce the tendency of a steel chip to weld to the tool. Such oil is advantageous when a good quality of machined finish is desired. For finishing operations, an oil with a high degree of oiliness generally is used.

There is a difference of opinion as to the desirability of using cutting fluids with cemented carbide tools. There seems to be a definite advantage in such a use, provided only that the work and tool are thoroughly flooded at all times that the tool is engaged with the work. A small or intermittent flow of cutting fluid on a carbide tool is dangerous, since the tool may be cracked by the fluid hitting the overheated tool. Rates of flow up to 40 and 50 gal per min are desirable on multiple-tool operations. When cutting fluid is used at the speeds desirable for cutting with carbides, it is necessary to shield the tool and work very thoroughly to prevent splashing of the fluid on the operator.

Cooling mechanisms have been introduced into the cutting-fluid circulating system to hold the fluid at a constant temperature. Such cooling, when adjusted to hold the work at room temperature during the cutting operation, tends to facilitate the accurate holding of size of the work piece, as well as to permit the use of increased cutting speeds.

QUALITY OF SURFACE. There are few data available as to the effect of cutting fluids on the quality of the surface produced. Where high quality of finished steel surface is required, a sulfurized mineral or a sulfurized mineral lard oil is generally used, except that water or soluble oil is generally used to obtain a high grade of finish with a spring tool on a lathe.

EFFECT OF QUANTITY OF CUTTING FLUID. When a cutting fluid is used it is particularly important that it be applied steadily; intermittent application may tend to crack the tool. When surfaces which are not easily accessible are being machined, special means should be provided for supplying the cutting fluid at the cutting edge of the tool; for example, oil holes through the boring bar used for boring deep holes.

Table 18, based on the work of Georg Schlesinger as reported in Ref. 6, gives an indication of the effect of variation in the quantity of fluid used on the rate of metal removal. Frederick W. Taylor had recognized the importance of an adequate quantity of cutting fluid and recommended the use of at least 3 gal per min on roughing cuts. It will be seen from Table 18 that the use of 3 gal per min of water results in a condition close to the maximum for the experiments on which this table is based.

Table 18. Effect of Quantity of Cooling Water on Permissible Cutting Speed

Rough turning chrome-nickel steel with high-speed steel tools; 0.079 in. depth of cut; 0.039 in. feed. Tool with 45-degree side-cutting-edge angle, 30-degree front-cutting-edge angle, sharp nose, 14-degree rake.

Water per min, gallons	0	0.2	1.1	2.2	3.3	4.4
Cutting speed, ft per min *	67	71	81	84	85	85
Relative rate of metal removal	1.00 †	1.05	1.21	1.25	1.26	1.27

* For 20-min tool life. † The dry condition is taken as unity.

For light cuts on steel, where the chip thickness is less than 0.015 in., use of a copious supply of cutting fluid permits use of cutting speeds approximately 16% greater than could otherwise be used. The effect of the cutting fluid appears to vary with the thickness of the chip from 16% for thin chips to approximately 50% for chips approximately 0.090 in. thick.

GENERAL RECOMMENDATIONS. Table 19 is based on experiment and on the recommendations of the suppliers of cutting fluid. Where possible, it is advisable to obtain the recommendation of a reliable manufacturer concerning the fluid to be used for a particular application.

Table 19. Recommended Practice for the Use of Cutting Fluid for Metals

Material Cut	Rough Turning and Planing	Finishing, Forming, and Turning and Planing
Cast iron	Dry Air blast Soluble oil, 50 to 1 Water, with 1 1/2% borax or soda	Dry Air blast Soluble oil, 50 to 1 Water, with 1 1/2% borax or soda
Malleable iron	Dry Air blast Soluble oil, 50 to 1 Water, with 1 1/2% borax or soda	Dry Air blast Soluble oil, 50 to 1 Water, with 1 1/2% borax or soda
Wrought iron or low-carbon steel	Soluble oil, 40 to 1 Sulfurized mineral oil Water, with 1 1/2% borax or soda	Soluble oil, 40 to 1 Sulfurized mineral oil Water, with 1 1/2% borax or soda
Medium-carbon steel	Soluble oil, 30 to 1 Sulfurized mineral oil Water, with 1 1/2% borax or soda	Soluble oil, 30 to 1 Sulfurized mineral oil Mineral lard oil Sulfurized mineral lard oil Water, with 1 1/2% borax or soda
High-carbon steel	Soluble oil, 20 to 1 Mineral oil Water, with 1 1/2% borax or soda	Soluble oil, 20 to 1 Mineral oil Water, with 1 1/2% borax or soda
Alloy steel Monel metal Nickel	Soluble oil, 20 to 1 Sulfurized mineral oil Water, with 1 1/2% borax or soda	Soluble oil, 20 to 1 Sulfurized mineral oil Water, with 1 1/2% borax or soda Mineral lard oil
Copper	Soluble oil, 50 to 1 Light mineral oil Sulfurized mineral oil Water, with 1 1/2% borax or soda	Light mineral oil Water, with 1 1/2% borax or soda
Brass or bronze	Soluble oil, 50 to 1	Light mineral oil
Aluminum, duralumin, pewter, zinc	Light mineral oil	Soluble oil, 50 to 1 Very light mineral oil Water, with 1 1/2% borax or soda

5. FACTORS AFFECTING RATE OF METAL REMOVAL

SET-UP MATERIAL. Provision of an adequate quantity of well-chosen and well-arranged set-up material saves much time in making ready the average job. More time is lost on nonrepetitive work through failure to provide an adequate equipment of set-up material, with racks or cabinets for keeping it in an orderly manner, than through any other failure on the part of management.

A supply of the frequently used equipment should be kept at each machine tool. The cost is low, when compared with the reduction in set-up time made possible by a carefully engineered equipment of make-ready material, and should prove to be a very profitable investment.

EFFECT OF LENGTH OF TOOL EXTENSION. Tools should be so clamped in the tool post as to be supported, as closely as possible, directly beneath the active cutting edge. Excessive overhang may cause chatter and make necessary an appreciable reduction of speed, feed, or both. The following figures, based on the shop practice of a leading manufacturer of machine tools in the use of large forged planer tools, give an indication of this effect:

Tool extension, in	0–8	8–12	12–20	20–34	34 and over
Reduction in cut and feed, %	0	25	50	60	65

EFFECT OF WORK SET-UP ON RATE OF METAL REMOVAL. The size of chip removed and the cutting speed used depend on the stiffness of the work, the amount it overhangs the supporting surface, the amount of unbalance, and the rigidity with which it is clamped. Experience has shown that at times, when the part is weak, and cannot be solidly held, it is necessary to reduce the rate of removing metal as much as 75% over that possible with stiff, well-held work.

EFFECT OF ATTENUATION OF WORK ON RATE OF METAL REMOVAL. When long, slim work must be turned on centers, the ratio between length and diameter of the work piece has an appreciable effect on the size of chip which may be taken, and on the cutting speed that may be used. Figure 15 shows the effect on production rates of variations in the ratio of unsupported length to the diameter of the work, when cutting SAE 1035 hot-rolled steel, with a tool having a $^1/_{16}$-in. nose radius, 90-degree entering angle, 6-degree nose drag angle, 14-degree side rake, 8-degree back rake, 6-degree relief angle, when taking a cut $^1/_{16}$ in. deep, with a feed of 0.033 in., used for the roughing cut. The finishing cut was taken with a similar tool having a $^1/_{16}$ in. flat, with a depth of cut of 0.015 in. and a feed of 0.033 in. The curves of Fig. 15 have been used successfully, in the shop in which they were developed, for setting production rates on a variety of long slim shafts approximately 1 to 2 in. in diameter, supported on centers and made in lots of 1 to 5. The extent to which they are applicable to conditions different from those for which they were developed is uncertain. They, at least, may be used as an indication of the reduction in the rate of chip production which becomes necessary as work on centers decreases in stiffness.

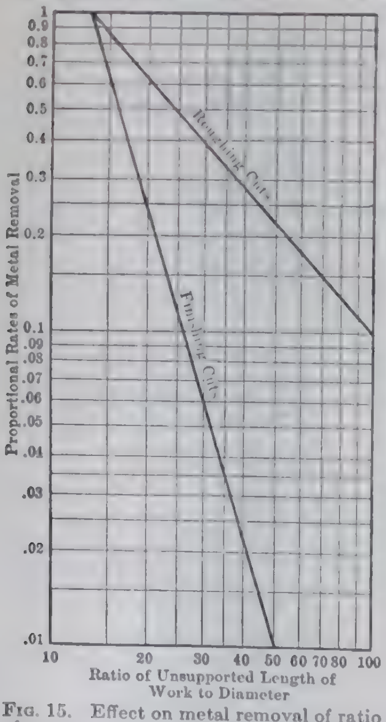

FIG. 15. Effect on metal removal of ratio of unsupported length and diameter of work. Steel work piece supported on centers.

CHATTER may be affected by several variables, of which these probably are the most important: (1) material cut; (2) chip proportions, as affected by *a*, depth of cut, *b*, feed, *c*, tool contour; (3) cutting speed; (4) rigidity of work; (5) stiffness of tool; (6) stiffness of work support; (7) stiffness of tool support; (8) vibrations caused by nature of design of machine tool, such as the gear ratios and tooth forms used; and (9) setting of tool with respect to work.

Many of these variables are fixed by design of the part to be machined and the machine tool available for doing the work. It appears that the best method of controlling chatter under a given set of conditions is to vary the chip proportions, cutting speed, the rigidity of the work support, or the setting of the tool with respect to the work.

Chip Proportions. Study of experimental data indicates that a cut taken with a relatively thick chip has less tendency to chatter than one taken with a thin chip. It would seem that it is desirable, in order to reduce chatter, to increase the feed, or to so change the shape of tool as to increase the thickness of chip with respect to its width. A tool having a nose radius greater than half the depth of cut is very likely to cause chatter unless a heavy feed is used.

Cutting Speed. A reduction in cutting speed may reduce or eliminate chatter. Some experimenters have reported that an *increase* in cutting speed may reduce chatter.

Rigidity of Work Support. Use of a center or follower rest frequently eliminates chatter. The use of opposed tools, to balance the normal components of the cutting pressure, is a very efficient method of reducing chatter.

Setting of Tool. It has been found that a change in the setting of the nose of a tool with respect to the lathe center may affect the amount of chatter. Carl G. Barth has told the author that in an aggravated case, setting of the tool nose considerably above the work center eliminated chatter. It is believed that this elimination resulted from the steadying effect of the contact between tool flank and work.

TOOL GRINDING. Improper grinding of metal-cutting tools leads to appreciable losses in production. Failure to use the most effective tool contours and angles requires

a reduction in the cutting speed. Grinding of tools by the individual machine operator causes a loss in production, as the machine tool must stand idle while tools are being ground. There is a growing tendency toward the grinding of all tools in a central tool room.

The type of grinding wheel to be used for tool grinding depends on the tool material, the area of contact between tool and wheel, whether the grinding operation is roughing or finishing, the surface of the wheel on which the grinding takes place, whether the tool is rigidly or loosely held with respect to the grinding wheel, and whether or not water is used.

Tables 20 and 21 summarize the recommendations of the two largest manufacturers of grinding wheels concerning the wheel that should be used under different conditions.

6. TOOL MATERIALS

The materials used for making tools for the cutting of metals may be classified in the following groups: (1) carbon tool steel; (2) low-alloy tool steels; (3) high-speed steel; (4) nonferrous alloys; (5) cemented carbides; (6) diamond.

CARBON TOOL STEEL. A tool steel containing little or no alloying metals, and with a carbon content of 1.10 to 1.30%, is used for cutting operations where a hard, keen cutting edge is required, at low cutting speeds, particularly when a high quality of finished surface is desired. It is used at times for forming tools, particularly where it is desirable to form the tool before hardening. It also is used at times where the size of the tool or work, coupled with speeds of available shop equipment, limit cutting speeds.

LOW-ALLOY TOOL STEELS include the fast finishing steels and some steels used for twist drills.

HIGH-SPEED STEEL is a steel containing at least 12% tungsten, 7% molybdenum, or an equivalent combination of the two, together with appreciable percentages of chromium and vanadium and, at times, cobalt. Analyses of the steels in most common use are given in Table 22. High-speed steel tools are much more generally used than those of other tool materials. They combine superior cutting qualities, strength, toughness, and relatively low first cost for a very wide range of general machining operations. Cutting qualities vary with composition. For history of the development of high-speed steel, see Ref. 2.

Table 22. Materials Used for Metal Cutting Tools

Type	Relative Cutting Ability	Carbon	Tungsten	Molybdenum	Chromium	Vanadium	Cobalt
			High-speed Steels				
18-4-1	1.00	0.70–0.75	18.0	....	4.0	1.0	....
18-4-2	1.03	0.80–0.85	18.0	0.75	4.0	2.0	....
18-4-3	1.06	0.85–1.10	18.0	....	4.0	3.0	....
14-4-2	1.00	0.70–0.75	14.0	....	4.0	2.0	....
Moly-tungsten	1.00	0.80–0.85	1.4	9.0	4.0	1.0	....
Molybdenum	1.00	0.80–0.85	....	10.0	4.0	1.0	....
			Cobalt Steels				
18-4-1 + 4% cobalt	1.07	0.70–0.75	18.0	0.5	4.0	1.0	4.0
18-4-2 + 7% cobalt	1.11	0.75–0.80	18.0	0.75	4.0	2.0	7.0
20-2 1/2-1 1/2 + 12% cobalt	1.12	0.80–0.85	20.0	1.00	4.5	1.5	12.0
14-4-2 + 4% cobalt	1.07	0.75–0.80	14.0	0.25	4.0	2.0	4.0
Moly-tungsten + 7% cobalt	1.07	0.80–0.85	1.4	9.0	4.0	1.0	7.0

Note. The relative cutting ability is based on relative cutting speed possible under uniform conditions of cut, tool life, and material cut.

In general, the cobalt steels may be run at higher speeds, particularly on heavy roughing cuts. They are more brittle and weaker, when hardened to secure maximum cutting speeds, and are appreciably more expensive than the standard high-speed steels. They must be hardened at temperatures approximately 50 F higher than the equivalent standard steels. Particular care, therefore, is necessary in hardening to prevent surface burning and decarburization. The use of cobalt steel is largely confined to tools in which the contour is formed by grinding after hardening, such as lathe and planer roughing and finishing tools, tool bits, and inserted blades for milling cutters.

NONFERROUS ALLOYS. There are several well-known tool materials in this classification, including Stellite, Tantung, and Rexalloy. These materials, which occupy a position between the high-speed steel tools and cemented carbides, can be used at cutting speeds 30 to 60% higher than those which can be used with high-speed steel, particularly when rough-machining cast iron, brass, and bronze. For use with old, and underpowered, machines, these tool materials may be all that is required to operate a machine tool at its full potential output.

CEMENTED CARBIDE TOOLS are made of various proportions of tungsten, tantalum, or titanium carbides, and a double carbide of tungsten and titanium, with cobalt matrix, formed into the desired shape by powder metallurgy and sintering, after which they can be formed only by grinding. The various carbides are characterized by extreme hardness, high transverse rupture strength, high resistance to compression, high modulus of elasticity, and considerable tendency toward brittleness. Their rate of thermal expansion is approximately half that of steel.

These materials are made in a number of grades, in which hardness, strength, and other characteristics are varied to make them particularly suitable for specific applications. Table 23, which shows the approximate comparison of the grades manufactured by seven leading producers of carbide tools, is in use in the plant of one of the leading automotive manufacturers. At present the manufacture of cemented carbide tools has not reached the degree of standardization obtained in the manufacture of high-speed tool steel, so that it is advisable to supplement the data given here by specific recommendations from the manufacturer whose tools are to be bought.

6. General purpose—steel.
7. Finishing cuts—steel.
8. Precision boring and light finishing—steel.
9. Wear materials—centers rest blades—gages.

A large percentage of the carbide tools used in the past have been in the form of tips brazed to a high-carbon or alloy-steel shank. This method of construction was apparently used at the outset because of the high initial cost of cemented carbide material. For the sake of economy, the smallest tip that seemed at all practicable was used.

The marked difference in expansion rates between the carbide tips and shank material has caused an increasing use of tips held in place mechanically by clamps or otherwise. The reduced cost of the carbide tips, in turn, has tended toward the use of much heavier tips than those originally used. It is claimed that such mechanically held tips not only give appreciably better performance than the brazed tips, but also make possible certain types of cutting which would otherwise be impracticable, notably high-speed planer operation and wide form cutting, as on chilled iron rolls. It seems probable that such tips are particularly desirable whenever the length of contact between tip and shank is at all large. One of the recent developments makes use of small rods of solid carbide material held in a holder in such a manner that the cutting surface is on the end of the tip. Such a tool makes possible the use of several cutting edges per grind, through revolution of the tip in the holder.

When tool tips are clamped on, the holder should be of hardened high-carbon steel, with both tip seat and tip base accurately ground to insure a seating of the tip throughout its entire area, and the avoidance of localized bending strains, which will tend to break the tip.

The high moment of inertia has been found to give added stiffness to narrow grooving or cut-off tools, thus reducing the tendency to deflect in either a vertical or horizontal plane.

The size of holders used with cemented carbide tools should be sufficient to give a considerable degree of rigidity, with a depth of shank under the tool blank of at least twice, and preferably three times, the initial tip thickness.

The usual carbide tool has a side-cutting-edge angle of 0 to 20 degrees, an end-cutting-edge angle of 5 to 25 degrees, and a small nose radius, usually 1/64 to 1/16 in., or approximately 1 1/2 times the feed per revolution.

There has been some tendency toward the use of negative-rake angles with cemented carbide tools. It is believed that the principal value of negative rake is for use when taking interrupted cuts. It has been found that a carbide cut-off tool operated satisfactorily with a positive back rake angle of 8 degrees and a chip breaker, whereas a negative back-rake angle of 5 degrees caused chipping of the cutting edge.

Chip breakers are usually employed with cemented carbide tools when cutting steel and other materials tending to give a continuous chip, as a means of chip control, although it is known that such a chip breaker reduces the cutting speed which may be used. There are several types of chip breakers, including those ground in the face of the tool tip and those formed by the use of an additional piece of carbide clamped in a suitable position. There are three usual forms of ground chip breakers: the parallel (shown in Fig. 16), the angular (shown in Fig. 17), and the groove types (shown in Fig. 18). See also Tables 24 and 25. The angular type is usually employed for light cuts, particularly finishing and semi-finishing cuts; the parallel type for light feeds, 0.005 to 0.018 in.; and the groove type for general purposes, where depth of cut varies and feeds from 0.012 to 0.065 in. are used.

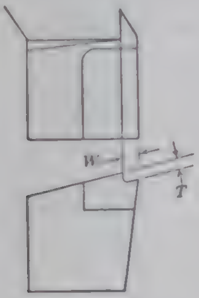

FIG. 16. Parallel type chip breaker. See Table 24.

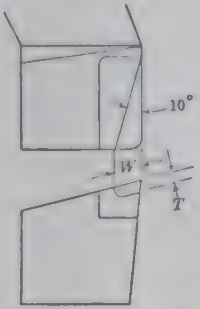

FIG. 17. Angular type chip breaker. See Table 24.

Feeds and speeds for use with cemented carbide tools cutting various materials are given in Tables 26, 27, and 28.

DIAMONDS. Diamonds cut and polished to the desired contour, and set in an appropriate form of holder, are used as cutting tools, particularly when it is desired to turn or bore a part with extreme accuracy; for example, the piston rod bushings of a gasoline engine. They usually are used for cutting relatively soft materials, as bronze, hard rubber, or molded synthetic resins, which may have considerable abrasive action on the tool.

7. HEAT TREATMENT OF TOOL STEELS

CARBON STEEL used for cutting tools should be hardened as follows:

Anneal. Heat to 375 to 1425 F and cool slowly, either in furnace or buried in an insulating material, as lime, ashes, or infusorial earth. Tools should be annealed after each hot or cold working, to reduce hardness and prevent the formation of a coarse crystalline structure.

Normalize. Heat tool uniformly to 1575 to 1650 F, until there is complete penetration of the heat and refinement of the grain, and cool in still air.

Preheat. Preheating of carbon steel tools is unnecessary unless the tool is exceptionally thick or is extremely irregular in shape. If preheating is believed to be necessary, the tool may be placed in a cold furnace which is brought slowly to hardening temperature; or it may be given a preheat of approximately 900 F before being placed in the hardening furnace.

Hardening. Carbon tool steel should be hardened at temperatures which vary with the carbon content of the steel:

Carbon content, %	0.65–0.80	0.80–0.95	0.95–1.10	1.10 and over
Hardening temperature, °F	1450–1550	1410–1460	1390–1430	1380–1420

Quenching. Carbon steel tools usually are quenched in a brine, consisting of sodium or calcium chloride in water, at about 70 F. They may be removed from the brine and placed in oil while still retaining a considerable portion of their heat.

Tempering. The hardening of steel tends to set up internal stresses which cause brittleness and a tendency for the cutting edge to break under cut. These conditions may be relieved by tempering as follows: To relieve strains, temper in oil at 300 to 375 F; to relieve strains and reduce brittleness, temper in oil at 375 to 500 F; to relieve strains and toughen, temper in lead at 500 to 650 F. The strength of an untempered carbon steel tool, as measured by the torsion impact test, is approximately one-fourth its strength when tempered to develop maximum strength.

HIGH-SPEED STEEL. The method employed and the temperatures used in the heat treatment of high-speed steel tools are very important and may easily have a greater effect on the cutting qualities of a tool than the particular grade and make of steel used. There is a tendency toward the use of lower quenching temperatures than those which will secure maximum cutting qualities of a tool, either to avoid brittleness or to prevent burning of the tool through the use of a furnace which does not afford full protection to the tool during the heating cycle. There is a growing tendency toward the use of salt baths, both for heating a tool to the required high heat and as a quenching medium. Such a heat treatment affords full protection to a tool against localized overheating, surface decarburization, and burning. It is quite possible to harden a tool, even when following what is generally considered good practice, in a manner to obtain a cutting capacity, measured in possible cutting speed, as much as 20% below the capacity inherent in the tool steel.

Annealing. All high-speed steel should be annealed before machining, after forging, or before rehardening. Pack bars or tools in annealing boxes, allowing about 1 $^1/_2$ in. between tools and sides of box, using lime, mica, infusorial earth, ashes or, at times, charcoal, as the packing medium. Each box should be sealed with fireclay, raised slowly to 1550 to 1650 F in the furnace, and allowed to remain at the annealing temperature long enough to anneal thoroughly. This time varies with the size of the tools and the weight of the charge; it will range from 5 to 10 hr. Boxes and work should be allowed to cool slowly in the furnace.

Preheat. Because of the low thermal conductivity of high-speed steel, it usually is brought to one or more intermediate temperatures in other furnaces, before it is placed in the hardening furnace. Tools usually are brought to a temperature of 1550 F in a single stage of preheat. Large, intricate tools may be heated to approximately 1000 F in the first preheat furnace and to 1550 F in the second, before hardening.

Hardening. High-speed steels must be heated to a point close to their fusion point, in an atmosphere as nearly neutral as possible, to develop maximum efficiency as metal cutting tools. This may be obtained by manual control of the fuel and air supply; by enclosing the tool in a container lined with a material which gives off carbon monoxide when heated; by heating in a closed chamber, the atmosphere of which is controlled by an auxiliary gas burner at the door; or by an inert gas, such as hydrogen, in a closed furnace chamber. There is a tendency toward the use of furnaces having some method of atmospheric control.

To obtain maximum practical cutting speeds, high-speed steel should be hardened at approximately the following temperatures:

	18-4-1	18-4-2	14-4-2	18-4-1+Co	14-4-2+Co	W-Mo	W-Mo+Co
Hardening temp., furnace, °F	2400	2400	2350	2450	2400	2250	2300
Hardening temp., bath, °F	2350	2350	2300	2400	2350	2200	2250

High-speed tools should remain in the hardening furnace sufficiently long to make certain that they have reached a uniform temperature and that the thermal reactions have taken place completely. For a modern furnace, in which there is little tendency to burn the surface and edges of the tool, the following times are approximately correct:

Tool thickness, in.	1/4	1/2	3/4	1	1 1/2	2	3	4	5	6	8	10
Heating time in furnace, min	2.0	3.0	4.0	5.0	7.0	8.5	12	15	18	20	25	30

These times are based on complete penetration of the heat. It frequently is undesirable or impracticable to use hardening times as long as those required for the larger thicknesses. For very thick tools, the practical procedure is to harden to a depth sufficient to give a satisfactory cutting edge, leaving the interior of the tool relatively soft.

Quenching. High-speed steel usually is quenched in oil, or an air blast. If large tools are cooled too rapidly, there is danger of causing shrinkage cracks, and it may be desirable first to quench in a lead bath at 900 to 1000 F, and to complete the quenching in oil.

Straightening When Quenching. A tool that warps during quenching may be straightened within the few minutes immediately following quenching. The tool cannot be straightened later, as it becomes hard within a very short time after quenching.

Tempering. After the hardened tool has been reduced to atmospheric temperature, it should be reheated to approximately 1000 to 1100 F, held at that temperature for 15 to 240 min, and cooled in air, in order to obtain maximum cutting efficiency and maximum transverse strength. This second heat treatment both increases the cutting qualities and the strength of the tool and reduces brittleness. The maximum strength under impact, as measured by the torsion impact test, is obtained when the tool is given a secondary heat treatment at 900 F.

Heat Treatment in Small Shops. Where it is impracticable to install a modern type of heat-treating furnace in a shop, tools should be purchased in the hardened condition, preferably in the form of bits. It is unwise to attempt to harden high-speed steel in the blacksmith's forge because of the uneven results obtained.

8. FORM TOOLS

There are four types of form tools in general use: (1) Flat tools, such as are used in engine lathes, having no back rake. (2) Flat form tools having a positive back rake. (3) Circular form tools, such as are commonly used on automatic lathes. (4) Dovetail form tools, which are frequently used on automatic lathes.

FLAT FORM TOOLS WITHOUT RAKE are similar in general appearance to the turning tools in common use. They are usually set to cut on center, and present no design difficulties, since the contour of the tool is identical with that of the finished piece. Such tools are commonly employed for producing small quantities of parts, because of the ease of making such a tool. No tool drawing is necessary, since the part drawing may be used by the tool room in making the tool. Such a tool does not cut freely, and must be operated at a much reduced speed to secure a good grade of finish; it is consequently undesirable for use with long production runs.

FLAT FORM TOOLS WITH A BACK RAKE must have the contour corrected to permit turning the drawing contours. The following equations give the necessary basis for designing such a tool to cut a contour of any desired shape. Figure 19 shows the conditions under which such a tool cuts, the nomenclature being: X = distance on tool, normal to front flank, to cut a difference in radii on work equal to $B - A$; A = minimum radius of surface cut; B = maximum radius of surface cut; a = back-rake angle of tool; and b = front-relief angle (also setting angle of dovetail tool).

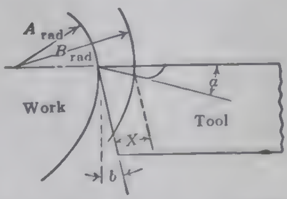

Fig. 19. Flat form tool with back rake, point of tool set on center.

When the point of the tool is set on center, as in Fig. 19, the distance X is given by the equation

$$X = [\sqrt{B^2 - (A \sin a)^2} - A \cos a] \cos (a + b)$$

When the point of the tool is set above center by a distance h at the minimum radius of the surface cut, the distance X becomes

$$X = [\sqrt{B^2 - \cos^2 a(2h\sqrt{A^2 - h^2} - A^2)} - \sqrt{A^2 - \cos^2 a(2h\sqrt{A^2 - h^2} - A^2)}] \cos (a + b)$$

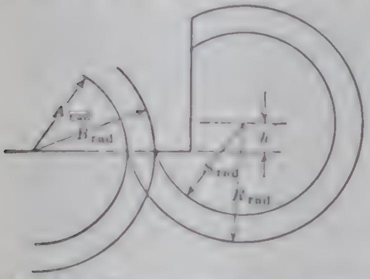

FIG. 20. Circular form tool, cutting edge of tool set on center of work.

For circular form tools, with the cutting edge on the center of the work and the center of the form tool above the center of the work by a distance h (Fig. 20), the radius S is given by the equation

$$S = \sqrt{R^2 - 2AB\sqrt{R^2 - h^2} + (B - A)^2}$$

Dovetail form tools, which are frequently used because of their inherent stiffness, may be calculated by the method given for flat form tools with positive back rake. When this is done, the setting angle is taken as the relief angle b of the formula for X.

LATHE WORK

By E. L. Murray

9. THE TURNING PROCESS

The turning process is a method of metal removal whereby a work piece is gripped in a suitable holding device and rotated under power against a single-point cutting medium which is fed radially or longitudinally to the axis of the work piece. The process is essentially one of surface generation, and thus true cylindrical, conical, spherical, or planar forms with coincident axes are reproduced in the work piece, depending on the direction of cutter travel.

COMMON OPERATIONS. Literal interpretation of the turning process is extended to include cutting operations such as turning, boring, facing, forming, parting off, drilling, reaming, tapping, and threading.

CUTTING MEDIA. Single-point shank-type tools are used for turning, boring, facing, forming, cutting off, and some types of threading operations, whereas multi-flute cutting tools are commonly used for drilling, reaming, tapping, and threading. Cutting tools used in the turning process may be made from various materials, the choice of which depends on such production factors as power available and condition of the machine tool, work finish required, work piece material, speed of machining as related to production requirements, and type of cutting operation. In the turning process, these cutter materials include hardened carbon and high-speed tool steel, the cast nonferrous alloys, cemented carbides, and to a limited extent diamonds. For further information, see the preceding chapter, beginning on page 23-22.

CUTTING FLUIDS. Factors are present in the relationship between work piece and cutting medium which may require the use of cutting fluids for optimum results. Machine tools used in the turning process are therefore usually equipped with suitable systems to provide coolants or lubricants in required quantities at the cutting area as well as properly designed guards to protect both machine and operator from deleterious effects of these fluids. For types and functions of cutting fluids, see Article 4 in this section.

FORMULAS. The following formulas give the relations between the diameter of a rotating work piece, number of revolutions, and cutting speeds. Let d = diameter of rotating work piece, inches; n = revolutions of work piece per minute; S = speed of work circumference, feet per minute. Then

$$S = \frac{\pi dn}{12} = 0.2618dn \tag{1}$$

or

$$n = \frac{S}{0.2618d} = \frac{3.82S}{d} \tag{2}$$

or

$$d = \frac{3.82S}{N} \tag{3}$$

Time Required for Any Given Cut. Let T = time, minutes, total length of cut; f = feed per revolution of work, thousandths of an inch; r = revolutions of work per minute; L = total length of cut, inches. Then

$$T = \frac{L}{fr} \tag{4}$$

Horsepower required in a machine tool for cutting metal. Let Hp = horsepower required; t = torque required, inch-pounds; n = revolutions of work per minute. Then

$$\mathrm{Hp} = \frac{tn}{63{,}000} \tag{5}$$

or

$$\mathrm{Hp} = \frac{2\pi Tn}{33{,}000} \tag{6}$$

where T = torque, foot-pounds.

When horsepower must be calculated as above and cutting torque is not known, the following formula applies. Let Hp = horsepower required; d = depth of cut; f = tool feed per revolution in thousandths of an inch; S = work speed in surface feet per minute; R_c = cutting resistance constant of material. Then

$$\mathrm{Hp} = \frac{dfSR_c}{33{,}000} \tag{7}$$

Cutting Resistance Constants, R_c:

Bronze (80-10-10)	95,000	SAE-4140 (Bhn 207)	275,000
Cast iron	175,000	SAE-4340 (Bhn 207-302)	275,000
Screw stock	225,000	SAE-52100 (Bhn 187)	315,000
SAE-1040 (Bhn 180)	250,000	SAE-1095 (Bhn 190)	315,000
SAE-1020 (Bhn 137)	275,000	SAE-4140 (Bhn 429)	345,000

A horsepower check list for material versus speed versus feed versus depth of cut is given in Table 1. These data assume use of single-point cemented carbide cutters and are based on extensive metal-cutting research conducted to determine power required to turn with carbide cutters at high speeds.

Tapping torque:

$$T = KrA \times 10^4$$

where T = torque, inch-pounds; K = material constant; r = radius from center of tap to center of gravity of cross section of area of metal being removed in one thread, inches; A = area of cross section of metal being removed by one thread of tap, square inches; rA = torque factor which may be calculated from Fig. 1.

Material Constants, K

No. 72 F.M. Brass	$K = 17.3$
17ST Aluminum	$K = 22.9$
No. 73 Naval Brass	$K = 33.1$
No. 3 Cast Iron	$K = 41.0$
X-1315	$K = 41.0$
X-1112	$K = 41.0$
X-1117	$K = 41.0$
A-4140	$K = 55.0$

Constants, K, for other materials may be estimated by their relative machinability to those listed above. Calculated torque should be doubled for dull cutting taps and dies.

Table 1. Horsepower Check List for Material versus Speed versus Feed versus Depth

(Reprinted by permission from Job Planning on the Turret Lathe, by E. L. Murray, *The Tool Engineer*)

The tabulated data provide a quick check on power requirements for various combinations of materials, depths of cut, and speeds and feeds. Common sizes of turret lathe drive motors are listed in the extreme left-hand column. The next column corrects the power for headstocks having an efficiency of 85%. For example, a 0.375 in. depth of cut in bronze, if at 600 surface ft per min and at 0.032 in. per revolution feed, would require 21.25 hp at the spindle. If the efficiency of this lathe headstock, considering all factors, is 85%, a drive motor rated at 25 hp would be required.

Hp at Motor		Hp at Spindle	Bronze (80-10-10)	Cast Iron	Screw Stock	SAE-1040 Bh-180	SAE-1020 Bh-137 SAE-4140 Bh-207 SAE-4340 Bh-207-302	52100 Bh-187 SAE-1095 Bh-190	SAE-4140 Bh-429

Torque for Taper Pipe Threads. Compute torque for a straight thread equivalent in pitch and diameter to the large end of the taper pipe thread. Multiply by 3 to compensate for 100% engagement of taper pipe tap or die.

EXAMPLE. What torque will be required to tap a 2 1/2 8 pitch straight thread in cast iron, assuming an 80% thread?

From Fig. 1, A for 8 pitch at 80% is approximately 36×10^{-4}. From Fig. 1, x for 8 pitch at 80% is approximately $4.6 \times 10^{-2} = 0.046$. Therefore

$$r = \frac{D}{2} - x$$

$$= \frac{2.5}{2} - 0.046$$

$$r = 1.204$$

Therefore

$$\begin{aligned} rA &= 1.204 \times 36 \times 10^{-4} \\ &= 43.34 \times 10^{-4} \end{aligned}$$

and

$$\begin{aligned} T &= KrA \times 10^{4} \\ &= 41 \times 43.34 \\ &= 1777 \text{ in.-lb} \end{aligned}$$

$$\text{Double torque for dull tap, } T = 1777 \times 2 = 3554 \text{ in.-lb required}$$

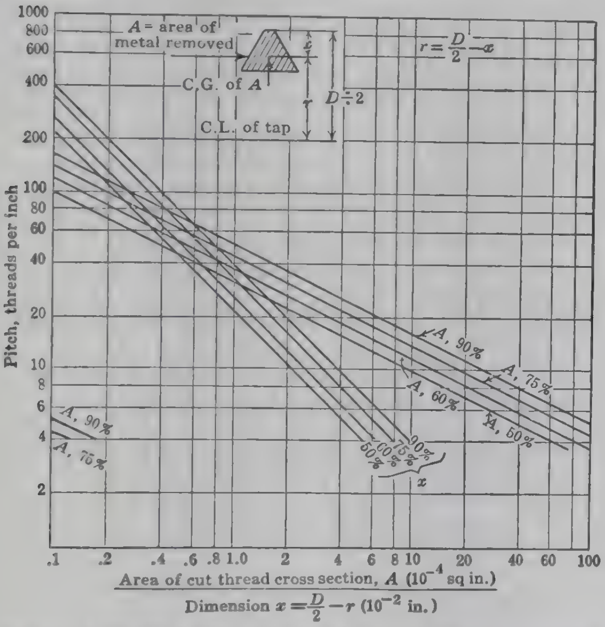

FIG. 1. Torque factor for American National form gun taps, at various percentages of full thread, is rA, where r is calculated as shown at top of cut, and A is obtained from chart.

RELATION TO OTHER MACHINING PROCESSES. Most machined parts at some point in their total routing incorporate a turning operation. For a very large percentage of these parts, the turning operations appear early in the routing and establish starting surfaces for subsequent gear cutting, grinding, honing, milling, lapping, etc., operations. The turning operation thus assumes a significant relation to the total machining of any given work part. It is understood that many machining operations such as milling and gear cutting are impractical on most types of turning equipment and then only under emergency or very low production conditions. However, it is frequently possible to duplicate on turning equipment certain finishes and dimensional control more generally expected from specific machine tools built for grinding, lapping, honing, tapping and threading, and like operations. For example, whether an engine lathe or thread miller is used to produce a certain thread involves factors of production, flexibility, and cost; and selection of the proper machine must be made on that basis.

Tolerances of 0.001 in. and less and finishes of 20 or less microinches, rms, are commonly held on turning equipment. Care should be taken to establish proper compatibility between the machine tool selected for the job and the blueprint limits, lot sizes, shop flexibility, and cost factors.

10. TURNING EQUIPMENT

Present designs in turning equipment are keyed to the omnipresent demand for lower cost production. Rapid strides in the cutting-tool industry have resulted in higher speed ranges, more power, engineered construction giving greater strength without sacrifice in accuracy, and improved maneuverability of machine elements.

Drives. Except for isolated applications, current designs of turning equipment provide for self-contained motor drives rather than overhead line and countershaft powering from a central motor source. Higher unit-power requirements per machine, machine portability, general improvement in shop lighting and cleanliness, operating efficiency, operator safety, and less cost of installation and maintenance are generally responsible for this change-over. Multiple unit V belts are in general use except for some instances where headstock speeds are obtained by shifting flat belts on cone pulleys rather than shifting gears in trains.

Constant-speed alternating-current drive motors are in wide use where gear trains and cone pulleys are used to determine spindle speeds. Direct-current motors are frequently used for some machine tools using variable-speed electronically controlled drives.

Headstocks. All-geared headstocks or boxes with gear trains, preferably arranged to give speed steps in geometric progression, are in common use today. Speed changing may be accomplished through shifting double or triple gears or by connecting and disconnecting fixed gear trains by clutches or by a combination of both. Gear shafts including spindles are generally mounted in anti-friction bearings, and teeth are usually ground on the form and rounded on the engaging face. Current headstocks are usually lubricated with a light engine oil through a spray or mist or splash system.

Bedways. These machine surfaces guide movable machine elements such as carriages and tailstocks and may be flat form, V form, or a combination of both according to the dictates of the manufacturer. Surfaces may be hand-scraped medium-hard nickel iron, ground surface flame or induction-hardened iron, or hardened and ground steel strips or blocks.

Spindle Noses. A trend toward uniformity of spindle noses has occurred in recent years to permit easy interchange of work-holding devices (see Ref. 1).

Tool Posts. (See Ref. 2.)

THE ENGINE LATHE. The engine lathe is a machine tool built to provide an extremely flexible means of machining a wide variety of work in small lots with a minimum investment in attachments and tooling. Engine-lathe practice requires the resetting of cutters for identical surfaces from piece to piece; hence for repetitive work, the hand turret lathe or automatic machine using preset cutters eliminates the costly repetition of resetting cutters to size. Conversely, when only a few pieces are required as in job shop work, repair shop work, or where production shop requirements are low, the engine lathe produces less expensively than the turret lathe or automatic principally because of the difference in set-up time and tooling cost. Because of improved designs and production methods, less difference in ability to reproduce accurate sizes exists today between engine lathes, turret lathes, or automatics, so that it is almost eliminated as a prime factor governing a choice between these machines for any given job.

Since the chargeable shop overhead is normally less on an engine lathe, it is frequently an additional advantage to perform simple-purpose cuts as secondary operations on an engine lathe for the purpose of controlling close limits of concentricity, parallelism, and size on work pieces.

Types of Engine Lathes. Engine lathes are variously classed as bench type and floor leg type, either of which may be equipped as a standard-change gear lathe or quick-change gear lathe for screw thread cutting and establishing power feeds.

Selection of Lathe Change Gears. For screw cutting with simple geared lathes, let G_s = number of teeth on stud gear; G_d = number of teeth on lead-screw gear; T_s = number of threads per inch on lead screw; and T_c = number of threads per inch to be cut. Select any gear for G_s. Then

$$G_d = \frac{G_s \times T_s}{T_c} \tag{8}$$

If the result is a fractional number, select another gear for G_s, and repeat the calculation. The equation assumes that the stud rotates at the same speed as the spindle. If these speeds are different, divide by the ratio of stud speed to spindle speed.

For screw cutting with compound-geared lathes, let $G_{1r}, G_{2r} \cdots G_{nr}$ = number of teeth on driving gears; $G_{1d}, G_{2d} \cdots G_{nd}$ = number of teeth on driven gear; T_s = number of threads per inch on lead screws; and T_c = number of threads per inch to be cut. Select at random all the driving gears and also all the driven gears except the last one. Then

$$G_r = \frac{T_c \times G_{1r} \times G_{2r} \times \cdots G_{nr}}{T_s \times G_{1d} \times G_{2d} \times \cdots G(n-1)d} \tag{9}$$

Transposing gears are used when it is desired to cut both English and metric screw threads on the same standard-change gear lathe. English transposing gears are used for cutting English screw threads on lathes having metric lead screws. Metric transposing gears are used for cutting metric screw threads on lathes having English lead screws.

For cutting multiple screw threads on lathes it is necessary to revolve the work in relation to its original position with respect to the lathe spindle as many parts of a turn as there are thread starts after the first thread has been cut.

Engine Lathe Attachments. Several attachments are available that increase the flexibility of the engine lathe. Among them are the collet chuck for work machined from bar stock, fixed and follower steady rests, four-position indexing turret for cross slide, six-position indexing turret for tailstock, milling and keyway cutting attachments, gear-cutting attachment, and grinding attachment.

Turning Tapers in a Lathe. Tapers can be turned in a lathe either by means of a taper attachment, which is supplied by many lathe manufacturers, or by setting the tailstock center a certain distance out of line with the headstock center. No exact rule for setting over the center can be given because the centers enter the work an indefinite distance. An approximate rule is: Divide the difference in diameters of the large and small ends of the taper by 2. Multiply the quotient by the ratio of the total length of the shaft to the length of the taper portion.

Miscellaneous Classes of Work. In addition to the many types of standard cutting operations covered by the *turning process*, the engine lathe may be used for certain additional special classes of work. They are knurling, filing and polishing, lapping, coil winding, spring winding, turning nonmetallic substances such as wood, fiber, and plastics; automotive service shop work such as armature truing, valve refacing, piston finishing, crankshaft turning and testing, and truing crankshaft bearings.

THE TURRET LATHE. The turret lathe is primarily distinguished from the tool room engine lathe by an arrangement of multiple-station tool holders or turrets, in place of the lathe compound rest and tailstock. These turrets permit the presetting of the total number of cutters required for the job and allow multiple and combined cuts from both turrets to operate on the work piece. This reduces cutting and handling time on repetitive work, and the function of the turret lathe in the production scheme is thus to produce lot sizes of work between those considered economical for the engine lathe and multiple-spindle automatics.

Types of Turret Lathes. Turret lathes are broadly classified as horizontal and vertical. Each type is available as a hand or semi-automatically controlled machine. Common usage limits the term *automatic turret lathe* to machines designed for chucking work only. See The Automatic Machine, p. 23-34, for details of the horizontal and vertical semi-automatic turret lathe.

The Hand-operated Vertical Turret Lathe. These machines are equipped with horizontal work tables designed with plain T slots or with built-in three-jaw combination or four-jaw independent chucks. Advantages of the horizontal table are immediately apparent for (1) large heavy work, (2) ungainly work with appended arms requiring a large swing out of proportion to small cutting diameters, or (3) overhanging work with lengthy distances between chucking and working or cutting areas. Such work may be laid down on the horizontal table and gripped with simple chuck jaws or clamps more easily and less expensively than is possible by gripping the same work against the vertical face plate or chuck used on the larger sizes of horizontal turret lathes. The capacity of the vertical turret lathe is normally designated by the diameter of the horizontal work table, and in this respect one manufacturer offers machines with tables 30 to 74 in. in diameter. Actual swing capacities run somewhat larger than the table diameter, depending on the presence of and working position of the side head.

Attachments. Thread cutting, drum scoring, angle turning, and scroll cutting may be accomplished on the vertical turret lathe by the use of suitable attachments applicable to either the main head or the side head. Turret and ram saddles may be swiveled on the cross rail within limits for taper turning and boring operations.

The Hand-operated Horizontal Turret Lathe. The horizontal turret lathe, although somewhat limited with respect to work types outlined in (1), (2) and (3) above, obtains its advantage on work of a more compact nature, the application and flexibility of taper and thread-cutting attachments and power-holding devices, and to the fact that many sizes of horizontal turret lathes are built with overlapping capacities, thus permitting a most efficient correlation of work range to machine size or mass.

The basic fact that a horizontal turret lathe is so constructed permits free interchange of chucking and bar stock jobs on the machine with the use of proper tooling. Horizontal turret lathes are subclassified as bar and chucking machines. The basic machine may be equipped with suitable tooling and work-holding devices for either or both types of work.

The horizontal bar or chucking machine may be further classified as ram type or saddle type. The ram type is built in the smaller capacities handling bar sizes up to approximately $2\frac{1}{2}$ in. in diameter for round stock and with chucking swings up to about 20 in. in diameter. The ram type is so named from its hex turret, slide, and saddle construction.

That is, the indexing hex turret is mounted on a ram slide guided through its stroke by a saddle which, though adjustable on the bed, is clamped in one position for any particular job. The indexing stroke of the ram is hand operated through a turnstile, rack and pinion, and power stroke by clutch engagement to the power feed train. Because of this ram construction its principal limitation is the length of the work stroke which varies with the size machine from about 4 to 15 in. Its principal advantage lies in the close correlation possible between machine and work size. Ram-type turret lathes may be powered with drive motors ranging between 3 and 15 hp.

The saddle-type turret lathe is designed with the indexing hex turret mounted directly to the saddle, without the use of an intermediate ram, the saddle in turn sliding directly on the bedways. This, in effect, greatly increases its length of work stroke compared to the ram machine, the only limitation being in the given length of the bed. Saddle machines are available with bar chuck capacities up to 6 in. round, and chucking swings up to approximately 30 in. in diameter. Machines of this type are powered by drive motors of 15 to 50 hp.

Turret Lathe Attachments. The flexibility of turret lathes is greatly enhanced by a variety of attachments. Discounting the wide variety of standard work-holding devices and standard tool holders, which in themselves make the turret lathe a versatile producing unit, several types of threading and taper attachments are available.

Screw Cutting. Threads in production may be cut from the hexagon turret by taps and dies in one pass or they may be generated by single-point tools with suitable lead control from the cross-slide carriage on ram-type machines and from the hex turret of a saddle-type machine, provided the latter is equipped with a cross-sliding hex turret. There are four types of threading attachments: (1) leading-on attachment for the ram-type turret lathes, (2) leader and follower attachment for the cross slide of ram-type machines and for both the cross slide and hex turret of saddle-type machines, (3) change-gear full-length lead screw for the cross slide of ram machines and the cross slide and hex turret of saddle-type machines, and (4) full-length lead screw with quick-change gear box for the cross slide of ram machines and the cross slide and hex turret of saddle machines. Changes in pitch for different threads are obtained with (1) and (2) by changing leaders and half nuts in the threading attachment. Separate replaceable change gears in the head end gear box are used to establish pitch for (3), and different pitches are determined by (4) through changing the position of the tumbler lever in the quick-change gear box.

Taper Attachments. Tapered surfaces may be produced on turret lathes by taper attachments or compounds. Simple contours may be produced with the taper attachment by substituting a profile guide plate for the straight plate or by the use of special contouring devices.

Steady Rests. Fixed-position steady rests may be used on turret lathes for the same work-holding requirements as found in the case of engine lathes. They are usually built to special specifications and may be (1) of the closed type, where the carriage may work on either but not both sides of the rest, or (2) of the open type, which permits free travel of the carriage on either side of the steady rest when cuts must be taken on both ends of the work piece during the course of one chucking.

THE AUTOMATIC MACHINE. This machine is profitable for producing larger lots of work parts where longer set-up times and frequently greater tool cost can be prorated over a large enough number of pieces so as not to endanger the cost savings per piece accruing from automatic cycling. Secondary advantages of automatic machinery are (1) the possibility of spreading unit labor costs over more than one machine and (2) removing all or most of the human element from the time cycle.

Types of Automatics. These machines may be broadly classified as: (1) full-automatic, where the entire production cycle is automatic including feeding of stock material, such as in bar work or hopper and magazine-fed set-ups, and (2) semi-automatic, where the cutting and index cycles are automatic, except that work parts are manually loaded and unloaded as in the case of chucking jobs.

Machines in either of these classes may occur as single- or multiple-spindle construction. Single-spindle semi-automatics are built in horizontal and vertical designs. Horizontal single-spindle semi-automatics are subclassified as general-purpose tool slide lathes, special-purpose tool slide lathes, and turret lathes.

The Single-spindle Full Automatic. This type of machine is invariably used for producing parts from bar stock in lot sizes between the hand turret lathe and multiple-spindle full automatic. The principle of combined cuts for time savings is effectively realized on this machine although it is not considered standard practice to split up cuts between tool stations as in the case of multiple-spindle machines. No consistent saving in time per piece is ordinarily realized over identical jobs done on hand turret lathes. The principal advantages of the machine are the elimination of the human element and its adaptability to multiple-machine operation by a minimum of operators and set-up men, through which factors lower costs per piece are usually realized over the similarly tooled job on the hand-operated bar turret lathe.

Single-spindle full-automatic bar machines are available in a variety of capacities. The uni-spindle design permits the speed of the spindle to be changed in simple ratios for greatly different types of cuts as turning and tapping, or forming and facing, without sacrificing tool feed or cutter life in favor of an abnormally high cutting speed set by other cutting operations on the same job, as may be true in multiple-spindle setups.

Speeds and feeds are set and controlled variously by clutches, speed and feed change gears, standard and special strip and disk cams, and electrical rheostat controls, depending on the manufacturer.

Cuts taken with circular or dovetail forming tools, whereby part or all of the exterior work piece contours may be finish machined easily from the cross slides, are more common on this type of machine than on the turret lathe bar machine.

Attachments. Auxiliary attachments are available for single-spindle bar automatics for performing added work on either end of the work piece. A pick-off arm allows index drilling, cross slotting, rear end drilling, threading, burring, etc., after the work has been parted off from the bar. Similar operations can be performed on the work prior to parting off by special attachments on the turret or cross slides.

Scope. Types of work ideally suited to this machine are all sizes and forms of studs, pins, washers, nuts, shafts, etc.

The Multiple-spindle Full Automatic. For production of bar stock work in large lots this machine is unique. It combines the previously cited advantages of automatic cycling with substantial reduction of time per piece over the hand turret lathe and single-spindle machine.

There are several basic principles of operation on a multiple-spindle automatic. (1) A number of tools are made to cut simultaneously. In this manner, during the operation of the tool with the longest cut, all other tools complete their operation. Therefore, the time it takes to perform the longest cut plus the constant idle time of the machine for indexing, traversing, etc., is the machining time for the component. Since there are always n components, n being the number of spindles in the machine, partly but successively machined, a finished component is obtained with each index of the spindle carrier. Therefore, it is standard practice on machines of this type to split up individual tool operations to reduce slide travel and shorten total production time. (2) Each machine set up has a particular operation which governs the machine spindle speed. All other speeds (in terms of surface feet per minute) for all other operations are directly proportionate to cutting diameters. (3) Each machine setup includes a particular operation which governs the feed gear selection. Feeds for all other operations are in direct proportion to the length of cut. (4) Each machine setup has only one spindle speed, and high differentials in required cutting speeds for tools within the cycle are obtained by attachments.

To achieve the most economical performance, it is important that every tool has only the feed stroke required for its operation during the whole cycle time. Feed strokes on currently available multiple-spindle automatics are adjusted by (1) standard or special replaceable cams and (2) quadrant arm mechanisms which are infinitely adjustable within the limits of the stroke.

Tool feeds on the principal makes of multiple-spindle automatics are obtained by (1) changing feed gears and (2) quick-change selective gear box.

Spindle speeds are selected by means of change gears in multiple-spindle full automatics. Because of the inherent designs of multiple-spindle carriers, it is mandatory that all spindles rotate at one speed. This speed is selected from a range of available speeds as being most efficient for the types of cutting operations in the cycle.

ATTACHMENTS. Since automatics of this type may have four, five, six, or eight spindles over which the work part may be successively machined, several types of attachments have been developed to speed up production and also perform miscellaneous operations otherwise done on additional machines. These attachments permit reaming, tapping and threading, recessing, high-speed drilling, slotting, cross milling, and knurling, and include pick-off devices for finishing back or cut-off ends after parting.

SCOPE. Because of the large number of work stations available on the multiple-spindle automatic, the scope of jobs handled is greatly expanded. Main limitations controlling scope are (1) collet capacity, (2) maximum length of feed stroke, (3) depth of holes drilled, and (4) types of fits required for tapping and threading operations.

The Multiple-spindle Semi-automatic. This type of machine may be vertical or horizontal. If horizontal, the collet chucks and bar feeds of the full automatic are replaced by two- or three-jaw power-operated chucks, and the work parts must be loaded and unloaded manually.

The horizontal semi-automatics are generally available in four, five, six, and eight spindles, and the capacity of each machine is expressed by the diameter of mountable chucks. Although the semi- and full automatic horizontal machines are generally identical except for chucking devices and are available in similar spindle combinations, they are not offered to handle bar and chucking work interchangeably as are hand turret lathes.

The vertical multiple-spindle semi-automatic also operates on the theory of machining a work part progressively from cutter station to station. They are available in four, six, eight, twelve, and sixteen spindle combinations with chucking capacities ranging from 10 in. to 34 in. in diameter, depending on the spindle combination. From this it may be assumed that for large work of the proper complexity and rated production requirements, this type of automatic may be profitably tooled to secure the advantages of automatic cycling not offered by any other type of turning equipment large enough to handle this range.

The Single-spindle Semi-automatic. Like the multiple-spindle semi-automatic, this machine is available as a vertical or a horizontal machine.

The vertical single-spindle machine has all the design features and applications of the hand-operated vertical turret lathe, previously described, except that control units are applied to the turret, ram, and side heads which may be preset to eliminate all manual operations except loading or unloading. The presence of these automatic-control units does not eliminate the possibility of switching the machine to manual control at will.

Horizontal single-spindle semi-automatics are available in two types, (1) tool slide lathes and (2) automatic turret lathes. Tool slide lathes are a form of engine lathe without screw-cutting characteristics but with one or more power-fed automatic tool slides. Work may be chucked or mounted between centers and gang-turning or facing cuts taken on a work piece separately or simultaneously as required. Some slides may be set at angles for taper work. These machines may be used profitably for medium-size production lots on simplified work which would not require the full complement of tool stations available on the hand or automatic horizontal turret lathe. Automatic turret lathes retain all function of the hand-operated turret lathe in addition to the usual advantages of automatic cycling.

11. COST ANALYSES

Certain fundamental relationships exist between the relative productive capacities of machine tools in the turning field and the investment required to obtain these potential capacities. Many factors enter into a production engineer's decision to tool a certain job on a given machine, not the least of which are (1) quantity of planned production of work piece, (2) expected production rate on the given machine, and (3) relation of cost savings to required investment.

The following examples of typical situations are offered as a guide to factors governing such analyses.

Example 1. An identical job setup on a ram-type turret lathe could use either (*A*) predominantly standard tools or (*B*) special tools. The following analysis is for the purpose of determining the quantity of work for which the cost per piece would be equal.

	Method A	*Method B*
1. Cost of standard tools	$1,234.75	$ 59.50
2. Consider depreciating standard tools with machine at 15-year rate—yearly depreciation	82.32	3.97
3. Consider 2000 hours of yearly depreciation—hourly depreciation	0.041	0.002
4. Considering standard overhead rate @ $2.50 per hour, excluding depreciation; then total overhead = line 3 plus $2.50	2.541	2.502
5. Assume rate for direct labor @	1.50	1.50
6. Total labor and overhead per hour = line 4 plus line 5	4.041	4.002
7. Total labor and overhead per minute	0.0673	0.0667
8. Cost of special items all depreciated in one lot	$ 197.00	$2,616.70
9. Production time per piece	5.2 min	2.2 min
10. Cost per piece (labor and overhead): line 7 times line 9	$ 0.34996	$ 0.14674
11. Difference in cost per piece: 0.34996 less 0.14674	0.20322	
12. Difference in cost of special items: $2,616.70 less $197.00		2,419.70

13. Then $2,419.70 divided by $0.20322 = 11,900 pieces, which is the point in production where the cost per piece is the same for both Method A and Method B. Method B would be justified only if the quantity exceeds 11,900 pieces.

Example 2. Method of determining quantity of work, where equal cost per piece exists, of an identical job setup on (A) a single-spindle semi-automatic chucking machine and (B) a multiple-spindle semi-automatic chucking machine.

	Method A	*Method B*
1. Cost of machine	$10,750.00	$17,325.00
2. Cost of standard tools	750.00	750.00
3. Total cost of standard items	$11,500.00	$18,075.00
4. Consider depreciating of standard items at 15-yr rate—yearly depreciation	$ 766.00	$ 1,205.00
5. Consider 4000 hr of yearly operation—hourly depreciation	0.19	0.30
6. Considering standard overhead rate @ $2.50, excluding depreciation, total overhead = line 5 plus $2.50	2.69	2.80
7. Direct labor	1.50	1.50
8. Total labor and overhead per hour	4.19	4.30
9. Total labor and overhead per minute: line 8 divided by 60	$ 0.07	$ 0.072
10. Setup time	1.5 hr	4 hr
11. Setup cost: line 8 times line 10	$ 6.29	$ 17.20
12. Cost of all special items depreciated in one lot	350.00	700.00
13. Total of special item and set-up cost: line 11 plus line 12	$ 356.29	$ 717.20
14. Production time per piece	0.9 min	0.33 min
15. Cost per piece (labor and overhead): line 9 times line 14	$ 0.063	$ 0.024
16. Difference in cost per piece: 0.063 less 0.024	0.039	
17. Difference in cost of special items: $717.20 less $356.29		360.91
18. Then 360.91/0.039 equals 9216 or the number of pieces made on each machine at equal cost		

Proving above: 0.063 (cost per piece, labor and overhead) times 9216 plus $356.29 (special items and setup) equals $936.89; and 0.024 (cost per piece, labor and overhead) times 9216 plus $717.20 (special items and setup) equals $938.38

The cost per lot of 9216 pieces is virtually equal on both machines. Obviously, the cost per piece will be less on the multiple-spindle machine as the quantities are increased, and the lower cost per piece will be attained on the single-spindle machine as the quantities decrease.

EXAMPLE 3. Method of determining amount of production required to justify a faster but costly producer A instead of a less-expensive but slower producer B.

Fast Producer A

				Depreciation per year	Depreciation per minute
Machine A cost	$13,877.00	@	6.6% per yr =	$ 915.77	$0.0076
Tools cost	2,895.00	@	100% per yr =	2,895.00	0.0240
Total equipment	$16,772.00			$3,810.77	
Labor @ $1.50 per hr and overhead @ $2.50 per hr excluding depreciation = $4.00 per hr or					0.0660 per min
				Total charge	$0.0976

Machine A produces one piece in 2.8 min flat time or at rate of 3.5 min (48 min hour) steady production.

Therefore,

Cost per piece = 3.5 × 0.0976 = 0.3423

Slow Producer B

				Depreciation per year	Depreciation per minute
Machine B cost	$7,274.00	@	6.6% per yr =	$ 480.08	$0.004
Tools cost	1,547.00	@	100% per yr =	1,547.00	0.013
Total equipment	$8,821.00			$2,027.08	
Labor @ $1.50 per hr and overhead @ $2.50 per hr, excluding depreciation = $4.00 per hr or					0.066 per min
				Total charge	$0.083

Machine B produces one piece in 4.5 min flat time or at rate of 5.63 min (48 min hour) steady production.

Therefore,

Cost per piece = 5.63 × 0.083 = 0.4674

Savings per piece when made on A machine 0.4674 less 0.3423 = $0.1251

A yearly depreciation charges	$3,810.77
B yearly depreciation charges	2,027.08
Difference	$1,783.69

This difference must be paid for out of the savings made by machine A to warrant its purchase.

Saving per piece when made on A machine is $0.1251. A machine makes one piece in 3.5 min or 136 pieces per 8-hr day; hence savings per day are 0.1251 × 136 = $17.01. Therefore, A machine must run 105 days to pay for $1,783.69 difference in annual depreciation. The manufacturer must make at least $1,783.69 divided by 0.1251, or 14,260 pieces per year to warrant purchase of A machine.

EXAMPLE 4. A typical replacement statement outlining the conditions under which an obsolete model machine may be replaced by a modern machine of the same type. Time to produce one piece on obsolete machine is 93 min; on modern machine 31 min.

Assume direct labor	$1.50 per hr
Assume factory overhead, excluding allowances for depreciation	2.50 per hr
Total	$4.00 per hr
or	$0.066 per min

Average cost per piece on obsolete machine: 93 min × 0.066	$6.14
Average cost per piece on modern machine: 31 min × 0.066	2.05
Savings per piece	$4.09

Production per month with modern machine:

$$\frac{\text{60 min (hr)} \times \text{8 hr (per day)} \times \text{23 (working days)}}{\text{31 min per piece (new equipment)}} = \text{356 pieces}$$

Total savings per month will then be:

356 (pieces per month) × 4.09 (savings per piece)	$ 1,456.04
If the new equipment is kept busy 80% of the time, deduct 20% of $1,456.04 (savings per month)	291.21
Value of usable savings per month	$ 1,164.83
Investment in new equipment (machine and tools)	16,772.00
Less resale value of old equipment	1,500.00
Net cash investment	$15,272.00

The new equipment will pay for itself in

$$\frac{\text{\$15,272.00 (net cash investment)}}{\text{\$1,164.83 (usable savings per month)}} = \text{13.1 months}$$

The net profit return per year will be:

$1,164.83 (usable savings per month) × 12 months =	$13,977.96
Less 6.6% depreciation on $15,272.00 (net cash investment)	1,007.95
Net profit per year after depreciation	$12,970.01

The rate of net profit will be

$$\frac{\text{\$12,970.01 (the net profit)}}{\text{\$15,272.00 (the net cash investment)}} = 84.9\%$$

PLANER WORK

By John M. Walter

As a general rule, planers are used for generating flat surfaces. These may be in vertical, horizontal, or angular planes. Form planing of flat or curved surfaces is done with special tools. By the use of cam followers or tracer devices, surfaces which are curved transversely or longitudinally, or a combination of both, may be planed.

The extreme simplicity of operation, and of the cutting tools used and their application, makes the planer one of the most versatile of all machine tools. With very simple cutting tools and work-holding accessories, a wide variety of work can readily be planed. Particularly is this so on larger work pieces where the surfaces to be machined are frequently located in different planes and at angles to one another. In some cases the machined surfaces are located deep down in pockets and other hard-to-reach places. Such work can be machined on the planer with inexpensive tools. The heads can be quickly swiveled to the required setting for doing angular surfaces. On many modern planers power swiveling of the heads is built into the machine.

The initial investment for the machine and the cost and maintenance of the cutting tools are far less for the planer than for other equipment capable of machining surfaces on fairly large pieces.

A high degree of accuracy is obtained in planing because of the simple generating principle involved, the ease with which the cutting edge on the finishing tool is maintained, and the fact that the tool can be positioned readily and held in proper relation to the work. In the construction of machine tools, planing is used almost exclusively for finish-machining large bed and table ways, dovetails, slides, and other guiding surfaces.

12. TYPES AND SIZES OF PLANERS

THE DOUBLE HOUSING PLANER is the most common type. It has two uprights for supporting the cross rail. Four heads are usually used, two on the cross rail and one on each upright.

THE OPEN-SIDE PLANER has an upright or column on the right-hand side only. It can accommodate work of varying widths, as the work piece can extend out over the table on the left side. Where the work is extremely wide, it is sometimes supported on an auxiliary rolling support placed alongside the planer. Open-side planers usually have two heads on the cross rail and a side head on the column.

CONVERTIBLE OPEN-SIDE PLANERS have a removable upright on the left side. This upright may be bolted to the bed or may be movable transversely on a floor plate or runway. A side head can be used on the upright. By removing the upright the planer is converted into an open-side type.

MILLING PLANERS, which are combination machines, are used for planing, milling, boring, and drilling. Various combinations of heads can be used. Table speeds range from milling feed rates to fast planing and return speeds. On these machines various types of operations can be performed on a work piece in a given setting, resulting in greater accuracy and economy. Milling planers may be of the double housing, open-side, or convertible type.

SIZE OR CAPACITY of planers is designated by the maximum size of work that can be planed on the machine. Thus a 60 in. by 48 in. by 20 ft planer is one that can plane a piece 60 in. wide, 48 in. high, and 20 ft long.

HYDRAULIC PLANERS. The table on this type of planer is reciprocated by the use of one or more hydraulic cylinders secured to the bed, the piston rods being secured to the table. Sometimes the compressibility of the oil tends to cause jerky action of the table. A column of oil will, under ordinary conditions, compress approximately $^{1}/_{2}\%$ of its length when subjected to a pressure of 1000 psi.

POWER REQUIRED FOR PLANING. From the standpoint of metal removal in cubic inches per minute, per horsepower, planing is more efficient than any other type of metal cutting. Analysis of the chip formation will reveal a minimum of distortion and internal working of the material, compared to turning (except at very large diameters), milling, and drilling.

The power required for planing can be expressed approximately as horsepower $= DFSK$, where D is the depth of the cut, F is the feed or thickness of the cut, S is the speed in feet per minute, and K is a constant. For planing medium-hard cast iron, K equals 3, approximately; for free-cutting steel, 6; and for soft bronze, 1.5. The horsepower derived from this equation represents the net horsepower at the tool. The power required to drive the planer idle should be considered, particularly for large planers operating at high speeds, to obtain the gross horsepower.

PLANER MOTORS. Variable-voltage reversing motors are used almost exclusively in gear-driven planers. A motor generator set energizes the reversing drive motor. The speed of the motor generally is adjustable from 40 to 1200 rpm and is independently adjustable on the cut and return strokes. In the most commonly used types of drive, the motor develops its rated capacity at 250 rpm, and the torque is constant at speeds of 40 rpm upward. The speed where the torque begins to drop off depends on the capacity of the motor generator set. In many installations its capacity is double the rated horsepower of the drive.

The size of the motor required for a given size planer depends on the kind of work to be done, number of cuts taken simultaneously, size and length of the planer, operating speeds, etc., and when feasible all factors should be considered in determining the horsepower of the motor. For general-purpose work the following may be used as a guide. For 30-in.

planers 15 to 25 hp, 48-in. planers 35 to 50 hp, 72-in. planers 50 to 75 hp., and for larger planers 75 to 125 hp. It must be borne in mind that these values represent the rated horsepower at 250 rpm of the drive motor. At higher speeds, the horsepower depends on the size of the motor driving the generator, which in many cases is double the rated horsepower.

LOAD-CARRYING CAPACITY OF PLANERS. Damaged ways sometimes occur because of overload. Safe loading of cast-iron ways should not exceed 20 psi of projected way bearing area. Even then the planer ways must be accurately level, and a good lubricating oil, preferably an extreme pressure (EP) oil must be used. This value includes the weight of the table, which in itself produces a pressure of 4 to 10 psi of projected way bearing area, depending on the size and type of planer. Heavy work, as for example the rams of large drop hammers, must sometimes be supported on heavy longitudinal bars to avoid highly concentrated loading of the ways. When the work overhangs the table, as on the left side of open-side planers, high concentrated loads sometimes result, even though the work piece is not very heavy. When unusually heavy or overhung loads are encountered, careful analysis should be made to avoid overloading.

Nonmetallic table bearings recently developed by the G. A. Gray Company, will safely carry 50 psi, without danger of scoring.

13. CUTTING TOOLS

CARBIDE TOOLS are being used extensively for planing, there being several methods of applying the carbide tip.

The most common type of carbide tool has the tip brazed on the shank, the shank being recessed for the tip. Tools of this kind are readily purchased in various sizes and shapes for different kinds of cutting operations. New carbide tips are available for replacement of broken tips. They can easily be brazed on to the shank after the cracked or broken tip is removed by heating the tip and shank. In regrinding the tip on tools of this kind, the shank must be ground back to obtain clearance. For this reason the recess for the tip on the shank has to be remilled after some usage.

Tools having removable bits are widely used. The bits are held in the shank or holder by serrations and wedges. They can be removed from the holder while the holder is left in the tool block. It is apparent that the operator exerts much less physical effort in removing the small bit than in removing the complete tool. Planer tools, as a rule quite heavy, are held in place by four large studs which require the use of a heavy wrench. The removable bit may be made of high-speed steel, cast alloy, or carbide tipped.

Tools having a carbide disk clamped on a shank are frequently used. The disk can be rotated after unclamping for presenting a new cutting edge. It is clamped by one screw in the center of the disk.

Tools having clamped-on carbide tips are widely used and have the advantage that the tip can be removed without removing the shank or holder. The carbide tips are ground to the desired shape and angles in a fixture and are then ready for mounting in the shank. A backing-up screw in the shank is adjustable for advancing the carbide tip as it is ground back at the cutting edge. The shank is provided with a hardened steel insert for the contacting surface of the carbide tip. Both the insert and the tip are ground flat at the interfaces. The tip is held in place by a small clamp having one or two small screws. This clamp is not for the purpose of holding the tip against cutting forces, but only to hold the tip in place, as the tool is designed so that the cutting forces act against the restraining surfaces and against the adjusting screw.

When carbide tools are used on planers it is very important to lift the tools clear of the work on the return stroke to avoid chipping the cutting edge. Modern planers are equipped with automatic tool lifters for this purpose. It is important that the tool-lifter mechanism be accurately synchronized with the table movement to avoid dragging the tool back over the work piece for even a small distance. It must also reseat without shock; otherwise the accuracy of slide setting will be affected.

Forged steel tools are sometimes used, usually being made of high-speed steel. Sometimes a high-speed steel end is welded to the shank or the shank is faced with a piece of high-speed steel.

Double-cutting tools, for cutting in both directions of table travel, are used successfully in some very special applications. One such application is in planing the T part of T slots. A two-edged cutting tool is used, being fast on a trunnion which is caused to oscillate a small amount at each reversal of the table. After one side of the T slot is planed, the trunnion is rotated 180 degrees for planing the opposite side. With this type of tool, several slots can be planed simultaneously in considerably less time than was formerly required to plane one slot. Operators who formerly lifted the tools by hand, high out of the slot on the return stroke, express their appreciation of the new double-cutting method.

Gang tools can be used to advantage on many jobs. Such tools have three or more tools set in a holder, one behind the other, so that each tool takes its proportional share of the total feed. One type of gang tool employs carbide disks which can be rotated to present a new cutting edge, after the disks are unclamped.

TOOL SHARPENING. The planer operator should not sharpen the tools. It is much more efficient to have the tools ground in the tool room to fixed specifications. Once the tool angles for best results have been definitely established under actual operating conditions, it is easy to maintain these angles in the tool-grinding department.

14. SPEEDS AND FEEDS

The cutting speed depends principally on the material being cut and the cutting tool. The feed may sometimes be limited by the ability of the work piece to support the cutting forces. When three or four heads are used on the planer simultaneously, the power of the motor may limit the amount of feed that can be used. Table 1 shows approximate speeds and feeds for various materials and kinds of cutting tools. The most efficient cutting speed and feed can be determined only by actual trial on the job.

Table 1. Cutting Speeds in Feet per Minute

	For High-speed Steel Tools				For Cast Alloy Tools				For Carbide Tools			
Depth of cut	1/8	1/4	1/2	1	1/8	1/4	1/2	1	1/8	1/4	1/2	3/4
Feed	1/32	1/16	3/32	1/8	1/32	1/16	3/32	1/8	1/32	1/16	3/32	3/32
Cast iron, soft	95	75	60	50	160	135	110	95	300	235	190	165
Cast iron, medium	70	55	45	35	125	105	90	75	220	175	140	125
Cast iron, hard	45	35	25	.....	95	80	65	.....	140	110	.....	.....
Steel, free cutting	90	70	55	40	140	105	85	65	330	260	200	.....
Steel, average	70	55	40	30	105	80	60	45	280	220	170	.....
Bronze, soft	150	150	125	.....	*	*	*	*	*	*	*	*
Aluminum, free cutting	200	200	150	.....	*	*	*	*	*	*	*	*

* Maximum table speed.

FINISHING CUTS are made with broad tools, a coarse feed being used when cast iron, bronze, aluminum, and nonmetallic materials are planed. The tools are 1 to 1 1/2 in. wide, and feeds 1/4 to 1 in. are used. For the best quality of finish, the depth of the cut is 0.001 to 0.002 in. The finishing tool must be set so that its cutting edge is exactly parallel to the surface being planed.

For finish planing steel, the tool is frequently formed so that the cutting edge will be at an angle to the line of travel of the work piece. This angle, which may vary from 20 to 45 degrees, is best determined by trial. Covering the surface of the steel to be finished with heavy cutting oil minimizes tearing and improves the finish.

In general, finish planing is done at greatly reduced speeds in order to preserve the accuracy of the cutting edge of the tool.

SETTING UP WORK. Since cutting time has been so greatly reduced through the use of higher speeds it is important to also reduce the setup time to obtain maximum output from the planer.

When the work is repetitive, fixtures for holding the parts should be used. The fixtures must be carefully designed to clamp the piece rapidly without springing it. The locating surfaces must also be arranged to minimize the time for cleaning off the chips.

Setup plates can sometimes be used to reduce the standing time of the planer. Such plates are arranged for rapid mounting and removal from the planer table. Two or more plates must be used in order to remove and set up work on one or more plates while one plate is in use on the planer.

Sometimes duplex tables are used to reduce the standing time. Such tables are divided at midlength so that one-half can be unloaded and reloaded while work on the other half of the table is being planed. The standing half of the table can readily be positioned at the end of the bed through the use of a quick-acting latch, and valves in the ends of the tables where they join together automatically establish oil circuits for proper functioning of the lubricating system. The two tables can be joined together and operated as one piece for long stroke work.

Magnetic chucks are used for rapid setting up when planing thin plates of ferrous materials. These chucks are frequently used for planing taper gibs by placing the chuck on a wedge-shaped piece made to the proper angle.

In such cases where setup fixtures are not used and the work pieces are not of simple form, the surfaces to be planed should first be laid off. This work should be done on a layout plate before the pieces are brought to the planer. The layoff lines enable the planer operator to set the job up in less time than would otherwise be required.

TOOL SETTING. For many jobs a tool-setting gage can be used to good advantage, particularly for the rough and semifinish cuts. Such gages usually consist of a plate fastened to the planer table, at the rear of the work, and in line with it. The cutting tools can be set to the gage, thereby saving time and greatly minimizing the chance of errors occurring in the dimensions. Where such gages are to be used for a long period of time, the gaging surfaces should be of hardened steel. Tool-setting gage surfaces can sometimes be built into work-holding fixtures.

TABLE SPEEDS. The speed at which the table of a planer runs depends on the speed of the driving motor and the gear ratio of the driving gears. This gear ratio is expressed as the number of revolutions through which the motor must turn to move the table one foot. On high-speed planers the gear ratio is usually 4, and heavy-duty frog and switch planers operating at low speed have ratios of approximately 12. It will be apparent that for a given motor torque the table pull, or cutting force, will vary in direct proportion to the gear ratio.

TIME REQUIRED FOR PLANING. The time required to take one cut over a given surface depends on the length of the stroke, width of surface, feed per stroke, cutting speed, and return speed. The approximate time may be expressed as

$$T = \frac{W}{F}\left(\frac{L}{C} + \frac{L}{R} + A\right)$$

where T = time, minutes; W = width of surface to be planed, inches; F = feed, inches; L = length of stroke, feet; C = cutting speed, feet per minute; R = return speed, feet per minute; and A = added time required for reversals.

Under normal operating conditions, the value of A varies from 0.015 min for low motor speeds to 0.040 min for high motor speeds.

Table 2 may be used as a guide for estimating planing time for short strokes. The values given are approximate maximums for a medium-size planer having a gear ratio of 5.

Table 2

Length of Stroke, in.	Number of Strokes per Minute
8	40 to 52
12	32 to 42
18	24 to 32
27	17 to 22
40	12 to 16
60	10 to 13

15. DEVELOPMENTS IN PLANERS

A very large majority of the planers in use cannot be operated at speeds above 100 ft per min, and therefore are not suitable for using carbide tools. With modern planers, cutting speeds up to 250 ft per min and return speeds up to 400 ft per min are being used. Compared with its predecessor of 15 years ago, the modern planer makes 3 $^1/_2$ or more times as many strokes in a given time, and in most instances the metal removal is in the same proportion. Rigidity of the machines has been very greatly increased, the housings, cross rails, heads, etc., being larger and heavier.

The increased speed and acceleration of the table have necessitated new developments in the other components of the machine. The feed mechanisms used on older planers are not practicable for rapid starting and stopping of the feed as required for high-speed operation, because of their high inertia factor. The new planer feed employs a different principle, eliminating the destructive inertia effects of the former feed devices. The feed mechanism of a planer plays an important part in the operation of the machine, and it can can truly be said "A planer is no better than its feed."

The ways of a planer must be in good condition to stand up under the severe service of high-speed operation. In this connection the nonmetallic ways previously mentioned have proved to be entirely satisfactory in filling a long-felt need. Scoring of the bedways is eliminated, and distortion of the table from heat generated by friction is greatly reduced. It may be in order to explain at this point that, with the usual way construction, during high-speed operation the frictional heat causes the lower side of the table to elongate with reference to the top side, thereby causing the table to curl up at the ends. With the nonmetallic way, this curling is greatly reduced because of the heat-insulating qualities of the table-bearing material.

Better lubrication of the ways through a closed circuit, under pressure, floats the table.

For safety in operation, a table-stopping device is necessary when high speeds are used. Failure of the electrical control or equipment may permit the table to run away at greater than maximum operating speeds. At such speeds the table has sufficient stored energy to carry it farther than normal shop clearances permit. The stopping device acts as a brake immediately when the table leaves the bull gear, and normally stops the table in approximately one foot or less of travel.

Owing to the use of much longer drive motors, the old arrangement of placing the motor perpendicular to the planer has given way to an angular drive that places the motor behind the right-hand upright. In many installations much floor space is saved through the use of this drive as the planer can be placed closer to the wall. Hypoid or spiral bevel gears are used for the initial reduction.

METAL-WORKING SHAPERS

By A. G. Baumgartner

The shaper is a machine tool used primarily for producing flat surfaces in horizontal, vertical, or angular planes. The shaper also is used for machining curved surfaces, helixes, serrations, and special work involving odd and irregular shapes.

The metal-working shaper, like the planer. develops cutting action from straight-line reciprocating motion between the tool and the work. On the shaper, the tool is reciprocated and the work is fed sidewise. The horizontal shaper with the ram movement in the horizontal plane is the most common form of shaper. Vertical shapers, with ram movement in a vertical plane, also come in the metal-working shaper group. Vertical shapers are also known as slotters.

Types of shaper work often may be done on a milling machine or a planer. The shaper, however, excels in handling tool-room work, die-shop work, and small-lot manufacturing, owing to its great versatility and its flexibility and speed of setup. Setup costs and tool costs are comparatively small. Planing, contouring, internal shaping, and high-speed shaping are accomplished rapidly and economically with little need for special fixtures and with simple cutting tools. The metal-working shaper's unusual flexibility and its power to perform easily work which might be difficult or impossible on other machines make it a basic machine tool. The shaper is especially advantageous in machining tough die steels of great hardness and alloyed high-strength cast iron. Such steels are used in the forging field, while alloyed cast iron is widely used in glass molds.

16. TYPES AND SIZES OF SHAPERS

HORIZONTAL SHAPERS include the push-cut and draw-cut design. Almost all manufacturers of horizontal shapers build the push-cut, crank-operated type, which are built with cutting strokes 6 to 7 in. long in bench models on up through 36 in. long in heavy-duty models.

A typical push-cut shaper employs a rocker arm reciprocated by a crankpin mounted on the crankgear and adjustable radially, the crank mechanism being an application of the Whitworth quick-return linkage. The return speed is higher than the cutting speed for increased efficiency, the ratio being varied according to the design.

Horizontal push-cut shapers are also operated hydraulically, using a piston and cylinder to operate the ram. The cost of a proper hydraulic unit, the comparatively low efficiency of the hydraulic drive, and the problems in accuracy have influenced almost all domestic shaper builders to use the crank drive.

Horizontal shapers are furnished with either plain or universal tables. The universal table adds to the flexibility and versatility of the shaper and, in conjunction with the swivel vise, provides rotation on all three axes. Graduations on all three movements speed angular setups.

VERTICAL SHAPERS OR SLOTTERS. The typical vertical shaper, or slotter, has an operating mechanism similar in principle to that used on crank shapers. Vertical shapers are also operated hydraulically. The vertical shaper differs from the horizontal in that the ram is vertical and the table is rotary. The ram can be inclined slightly from vertical for angular work.

The table on a vertical shaper can be rotated about the vertical axis and also fed longitudinally and transversely. The flexibility of the rotary motion, together with the two-way horizontal feeding of the table on the vertical shaper, makes it a valuable tool for keywaying, slotting, and internal work. Vertical shapers are commonly built in maximum stroke length from approximately 6 to 36 in. Strokes of 48 in. and longer can be furnished.

HORSEPOWER REQUIREMENTS for fairly heavy cutting on shapers are given in Table 1.

Table 1. Horsepower Requirements for Shapers

Horizontal Shapers		Vertical Shapers	
Stroke, in.	Hp	Stroke, in	Hp
12	2–3	6	3
16	3–5	12	3–5
20	5	18	5
24	7 1/2–10	24	7 1/2–10
28	10	30	10
32	10–15	36	10–15
36	15		

Larger motors can be used for extra-heavy cutting, but they are rarely required because the demands of average cutting on shapers are well within the ratings given.

17. CUTS AND FEEDS

Because of the great variety of materials, cutting tools, and character of work, only general comments can be made on cuts and feeds. Horizontal shapers are commonly provided with a horizontal power feed range of 0.010 in. through approximately 0.200 in. and vertical power feeds on the head of 0.005 in. through approximately 0.100 in.

Vertical shapers have longitudinal and transverse power feeds with ranges approximately from 0.002 to 0.100 in. for small stroke machines, up to 0.150 in. maximum on 36-in. stroke machines. The rotary feeds on vertical shapers range approximately from 0.004 to 0.175 in. on a 20-in. circle. These figures are general and vary with particular machines.

The depth of cut is normally governed by the amount of material to be removed, how much the work will stand with regard to breaking out, deflection under the cut, and distortion from heat. The cut also depends on the character of material being cut and the limitations of the cutting tools.

Time required for shaping a flat horizontal surface is the result of WT/FS, where W represents the width of the work, F the amount of cross feed, S the strokes per minute,

Table 2. Cutting Speeds of Shapers

Strokes per min	Length of Stroke, in.																	
	2	4	6	8	10	12	14	16	18	20	22	24	26	28	30	32	34	36
	Average Cutting Speed, ft per min																	
10	5	7	10	13	16	18	21	24	27	30	32	33	35	37	39	41	43	45
15	6	10	15	19	23	28	33	37	40	43	46	50	54	58	61	64	67	70
20	7	13	20	26	32	38	44	50	55	60	65	70	74	79	83	87	91	95
35	12	23	34	45	55	65	74	83	92	101	110	118	125	133	140	147	153	159
50	17	32	48	64	78	92	106	119	131	145	157	168	179	190				
75	25	49	72	95	116	136	156	176	196	216								
100	33	65	97	129	160	190	220	250										
150	48	95	140	190	235	280												
200	65	127	190	255														
300	99	195	298															

and *T* the number of trips across the work to obtain the finish required. *F* may be different for each trip. *T* commonly falls within 1 to 3.

Cutting speeds are of consequence especially on horizontal shapers. Average cutting speeds for different lengths of stroke and strokes per minute on shapers with a typical return ratio are given in Table 2.

18. SHAPER WORK

The versatility of shapers should be emphasized again. Applications of the horizontal shaper include the following major functions.

SHAPING OR PLANING OF FLAT SURFACES. The majority of this work is held in a vise. The standard vise has a graduated base and can be set with the stroke, or at right angles to the stroke, or at any other angle required. Vises are furnished in a variety of types. The single-screw vise and the double-screw vise (Fig. 1) are the most popular. The shaper vise on the tilting top of the universal table gives great flexibility in angular shaping.

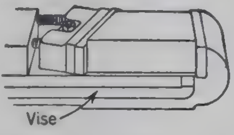

FIG. 1. Tapered workpiece in double-screw vise.

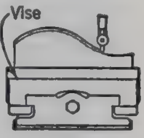

FIG. 2. Shaping contours.

Work can also be fastened directly to the shaper table. The surface gage and the indicator are two of the tools essential in setting up and checking work.

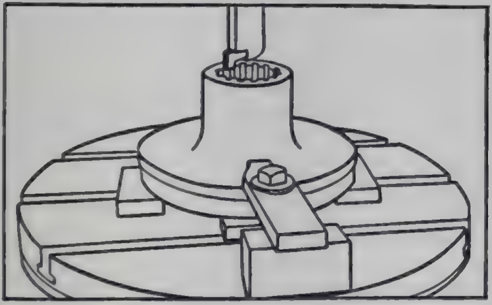

FIG. 3. Cutting internal splines on a vertical shaper.

CONTOURING, or machining irregular shapes, is another function of the shaper (Fig. 2). This operation can be done by operating the vertical feed on the head by hand while the cross feed is operated by power. For more difficult work, the cross feed is also frequently operated by hand in conjunction with the vertical feed on the head. For such operation, an additional or auxiliary control at the front of the table for cross feeding is helpful to the operator.

AUTOMATIC DUPLICATING equipment is available on shapers for developing contours and irregular surfaces. Automatic duplicating equipment can be had in elaborate forms for developing compound surfaces, such as the blade of a ship propeller, or in simpler form for curved surfaces that can be produced with straight-line cutting.

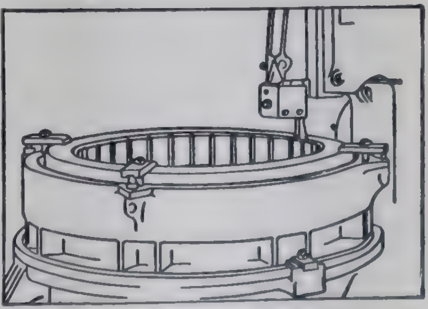

FIG. 4. Slotting on a vertical shaper.

KEYWAYING AND SLOTTING are usually done on a vertical shaper or slotter (Figs. 3 and 4). The horizontal shaper, however, is also used for this purpose (Fig. 5).

Internal shaping can include keywaying and slotting. Internal shaping, however, covers much more. The internal guides of valves, for example, are machined on horizontal shapers on a manufacturing basis.

CUTTING TOOLS. A great deal more attention can be given to cutting tools by the shaper user; incorrect and inadequate tools seem to be the rule rather than the exception. The usefulness and productivity of a shaper can be greatly increased by adequate cutting tools. Shapers, in general, can also be operated at higher speeds in most shops.

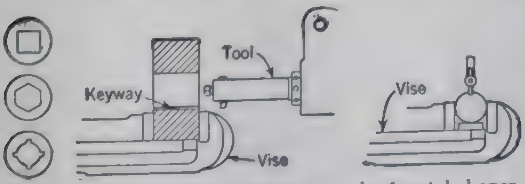

FIG. 5. Keywaying and slotting on a horizontal shaper.

The grinding of cutting tools is an enormous subject. The actual angles can be as varied as the classes of materials and the character of work. High-speed steel is commonly used on shapers today. The use of a round-nose tool is a common error, especially in cutting tough materials such as B die blocks. A tool with a very small radius, approximately 1/32 in., and with a straight cutting edge, gives the best performance. Such a tool should also be used on jobs that require excessive overhang of work or tools, and where there is a tendency for chatter. The sharp nose and the straight cutting edge, in general, are to be recommended. Negative front rake can be used with benefit on high-speed steel as well as carbide tools.

Tools and tool holders specially manufactured for both horizontal and vertical shapers are available from tool manufacturers. Shaper tools are also furnished in sets and for general purposes are quite satisfactory.

The use of the ordinary lathe tool on the horizontal shaper is another common error that should be avoided. The lathe toolholder supports the cutting bit at an angle and throws the cutting tip ahead of the shank of the holder. The deflection of the tool causes the tip to dig into the work, and the result is chatter and inaccuracy. The cutting point of a shaper tool should be near the center line of the shank so that the point will swing out of the work instead of digging in. Carbide holders which hold the bit parallel to and near the center of the shank are available. These holders should also be used for high-speed bits. Tools should be machine ground, not hand ground.

Carbides would seem to have limited application on shapers because they are usually associated with high production. Actually, the use of carbides is increasing rapidly because the modern shaper with its high speeds, fully automatic feeds, improved controls, and increased power is taxing the best high-speed steels. This is particularly true on die blocks, high-carbon, high-chrome steels, and special alloyed cast irons. Shockproof-grade carbides are already in regular use in machining these materials with complete satisfaction. A dependable fully automatic tool lifter that can operate at high speeds for many millions of operations is essential to the success of carbides on the shaper.

Like other machine tools, the shaper continues to develop and promises to enlarge its field of operation with the aid of better cutting tools and continually improved designs.

MILLING MACHINE PRACTICE

By Mario Martellotti and Hans Ernst

19. ANALYSIS OF THE PROCESS OF MILLING

FUNDAMENTAL CONCEPT. The milling process may be considered as a method of metal removal in which the portion of the work piece that is to be removed is projected into the space dominated by a rotating body carrying one or more individual cutting teeth. The profile of the finished surface produced on the work piece, therefore, is determined by the intersection of a plane, perpendicular to the motion of the work piece, and the outline of the body of revolution generated by the rotating cutter.

Two main classes of milling operations are:

1. **Face milling,** in which the finished surface is mainly parallel to the face of the cutter.
2. **Peripheral milling** (including slab and form milling), in which the finished surface is mainly parallel to the periphery of the cutter.

CHARACTERISTIC FORM OF MILLING CHIP. Because of the limited period of engagement of each tooth with the work piece, the removal of metal in milling is accomplished by the separation of small individual chips. The rotary motion of the cutter and the translatory motion of the work piece combine to produce a chip whose cross section varies from instant to instant as the direction of motion of a tooth changes with respect to direction of motion of the work piece. Chip thickness is a maximum at the instant that these motions are perpendicular to each other, and substantially zero when they are parallel.

SURFACE GENERATED IN MILLING. In peripheral milling, two distinct methods are used:

Up-milling. The work piece advances toward the cutter from the side where the teeth are moving upward. The cutter rotates against the direction of the feed. The chip thickness is a minimum at the beginning of the cut and a maximum at the end.

Down-milling. The work piece advances toward the cutter from the side where the teeth are moving downward. The cutter rotates in the same direction as the feed. The chip thickness is a maximum at the beginning of the cut and a minimum at the end.

Figure 1 compares the shape of milling chips produced by these two methods, the difference in shape being exaggerated by the use of a large feed per tooth. In both methods the path of a tooth through the work material is a curtate trochoid. Its actual shape varies with changes in rate of feed, diameter of cutter, depth of cut, and cutting speed. Figure 1 shows that the actual rake and clearance angles change continually as the tooth forms a chip. In up-milling, the actual clearance angle θ is greatest at the beginning of the tooth contact with the work, decreasing to a minimum value of θ_1 when the tooth leaves the work. The actual rake angle, however, has a minimum value α at the beginning of the cut, increasing to maximum value α_1 at the point of leaving the work. In down-milling, the actual clearance angle θ is least at the beginning of the cut and greatest, θ_1, at the end. The actual rake angle α is greatest at the beginning of the cut, and least, α_1, at the end.

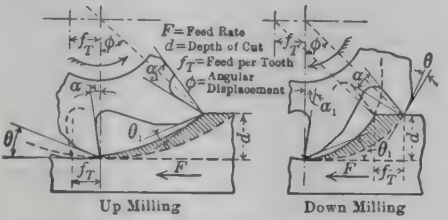

FIG. 1. Comparison of up milling and down milling.

In this respect, milling differs radically from other machining processes, like turning, planing, etc., in which clearance and rake angles remain constant throughout the cut.

CHIP FORMATION. Up-milling and down-milling produce surfaces of entirely different character, the reason lying in the nature of the process of chip formation. When a cutting tool engages a work piece, the material immediately ahead of the cutting edge is at first compressed and escapes by flowing in a direction parallel to the face of the tool. As the tool continues to advance, however, escape in this direction becomes increasingly difficult; the pressure on the tool rises; the stress in the material farther ahead of the tool increases, finally reaching a value great enough to cause rupture or flow in a plane roughly perpendicular to the face of the tool. If the material is relatively brittle, or the thickness of chip is great, a definite rupture occurs in this plane. The entire portion of severed material then moves out of the path of the advancing tool and permits the engagement of a fresh portion. The chip is not a continuous ribbon, but a series of individual segments more or less closely joined. This type of chip is known as a discontinuous chip (Fig. 2).

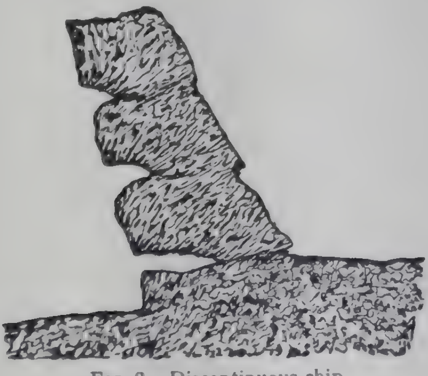

FIG. 2. Discontinuous chip.

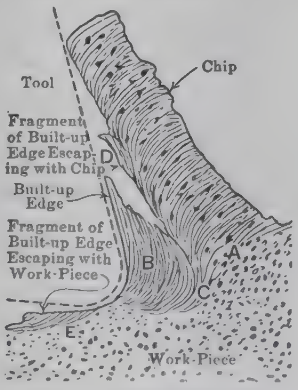

Tool
Chip
Fragment of Built-up Edge Escaping with Chip
D
Built-up Edge
Fragment of Built-up Edge Escaping with Work-Piece
B
A
C
E
Work-Piece

FIG. 3. Continuous chip.

If the material is relatively ductile, definite successive ruptures do not take place; instead, the material ahead of the tool yields by plastic flow over a broad region. As this material (A, Fig. 3) is forced out of the path of the advancing tool, it separates from the initially compressed portion B, which is held by frictional contact with the tool face. The body of the chip passes off as a substantially solid ribbon, with flow lines perpendicular to the tool face. The wedge-shaped portion B, with flow lines parallel to the tool face, remains to form the so-called *built-up edge*. This type of chip is generally known as a continuous chip. The built-up edge is added to continuously by material compressed at point C, but is periodically reduced by fragments, like D and E, torn off the chip and the work piece, respectively.

Roughness of a machined surface is due solely to the presence of fragments like E; consequently, for good finish, their magnitude should be kept to a minimum by so arranging conditions that the stable size of the built-up edge itself is a minimum. Such arrangements include: (1) decrease in chip thickness; (2) increase in rake angle; (3) increase in tool sharpness; (4) increase of cutting speed; (5) use of cutting fluid; (6) use of work material of lower ductility. (See Ref. 1.)

In *up-milling* the portion of the finished surface produced by a tooth is formed at the beginning of its contact with the work piece, when the chip thickness is extremely small. Hence, the built-up edge itself is very small, and the resultant surface is smooth and shiny. In *down-milling* an element of the finished surface is produced at the end of the tooth engagement with the work. With a ductile material such as a low-carbon steel, where the built-up edge is large, the built-up edge persists to the extreme end of the chip; thus fragments continue to escape, producing a somewhat torn finish similar to that obtained by planing or shaping. With a less ductile material, such as a high-carbon steel, the built-up edge is smaller; hence, the difference in finish between up-and-down methods of milling is less marked. (See Ref. 2.)

20. MILLING CUTTERS

Cutting materials generally used for milling cutters are of these types: (1) (*a*) carbon tool steel and (*b*) alloy tool steel (high-speed steel); (2) cast nonferrous alloys; and (3) sintered carbides.

CARBON AND HIGH-SPEED STEEL-CUTTING MATERIALS. Carbon tool steel and high-speed steel milling cutters are generally made in accordance with the standards approved by the American Standards Association. See Ref. 3 for discussions of the most commonly used types.

The classifications adopted are listed below. Although carbon tool steel is still used to some extent for screw slotting and slitting cutters, and other light-duty work, practically all heavy-duty milling cutters of these types are made of high-speed steel.

For most classes of work, high-speed steel cutters can be run 2 to 2 $^1/_2$ times as fast as carbon steel cutters.

A. CLASSIFICATION BASED ON RELIEF OF TEETH. 1. **Profile cutters** include all forms of cutters which are sharpened by grinding on the periphery of the teeth, the clearance angle (or relief) being obtained by grinding a narrow land back of the cutting edge. Where the cutting edges are of curved or irregular shape, they are designated *shaped profile cutters.*

2. **Formed cutters** include all cutters where the eccentric relief back of the cutting edge is of the same contour as the cutting edge itself. These cutters are sharpened by grinding the face of the teeth.

B. CLASSIFICATION BASED ON METHOD OF MOUNTING. 1. **Arbor Cutters.** A cutter with hole for mounting on arbor.

2. **Shank Cutters.** All cutters having either a straight or taper shank integral with the cutter.

3. **Face Milling Cutters.** All cutters designed to be attached directly to the spindle nose, or to the end of a short arbor known as a stub arbor.

C. CLASSIFICATION BASED ON TYPE AND USES. The commonly used types of cutters and the work to which they are adapted are discussed below.

The plain milling cutter (Fig. 4) is a cylinder with teeth on the circumferential surface only. It is used to produce a flat surface parallel to the axis of the cutter. Plain milling cutters are made in a wide variety of diameters and widths, for the various requirements of slab milling. They generally have helical teeth. The helical form enables each tooth to take a cut gradually, thus reducing shock and minimizing tendency to chatter. Cutters with a helix angle of 25 to 45 degrees, commonly, but incorrectly, are termed *spiral mills;* if helix angle is more than 45 degrees the cutter generally is known as a *helical mill.*

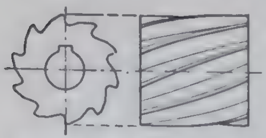

Fig. 4. Plain milling cutter.

The helical mill, which may be either of the shank or hole type, is free cutting and particularly desirable for light cuts on soft steel or brass. It can be used to advantage for profiling work, such as cam milling, and for milling intermittent surfaces. The shank type, with pilot end, commonly is used for elongating slots. For general slab milling, the helical mill is not as efficient as the common "spiral" mill.

The side milling cutter is a plain milling cutter of cylindrical form with teeth on the circumferential surface and on both sides. The side teeth extend a portion of the distance from the circumference to the axis. Half side and interlocking side milling cutters also are made. Side milling cutters are used in a large variety of work. Two or more of them often are placed on the same arbor with a space between them; they are then known as straddle mills.

Straddle mills are used to advantage where the work is to be milled on two parallel sides, e.g., bolt heads and tongues.

Interlocking cutters are used to mill slots to a standard width. They are maintained at a constant width by thin shims or collars between the inner hubs.

Staggered tooth milling cutters (Fig. 5) are cylindrical cutters with the cutting teeth on the circumferential surface only. Alternate teeth are of opposite helix angle. (See Fig. 5. The side teeth extending from the circumference a short distance towards the axis are for chip clearance only. They are not ground for cutting purposes. This type of cutter, used to obtain exact width of slots, is the most efficient type for milling slots where depth exceeds width. Because of the alternate right- and left-hand helix angle of the teeth, with considerable undercut, these cutters can remove large amounts of metal without vibration or chatter. The free-cutting action makes possible an increased feed and speed, without detriment to the production of smooth, accurate work.

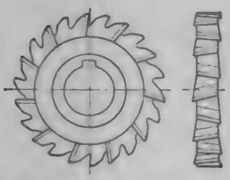

Fig. 5. Staggered tooth cutter.

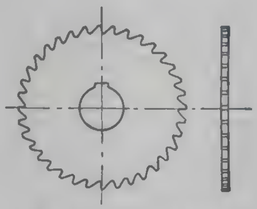

Fig. 6. Slitting saw.

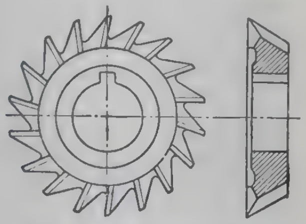

Fig. 7. Single-angle cutter.

Metal slitting saws (Fig. 6) are plain milling cutters with sides relieved or "dished" to give side clearance. They generally are made $^{3}/_{16}$ in. thick or less, and usually have more teeth for a given diameter than a plain milling cutter. They are used to cut off work, or to mill very narrow slots. Slitting saws also are made with side teeth similar to side milling cutters, and with staggered teeth, similar to staggered tooth milling cutters. The metal slitting saw with staggered teeth usually is made $^{3}/_{8}$ to $^{3}/_{16}$ in. thick, and is used for heavy sawing in steel.

Angle milling cutters are made both **single angle** and **double angle,** with teeth on the conical surfaces. (See Figs. 7 and 8.) Single-angle cutters are made both with and without teeth on one or both of the flat sides. Angle cutters are used for various fluting operations, or for milling the edge of a piece to a given angle.

Formed cutters usually have a curved tooth outline and are used in milling contours of various shapes. They may be divided into two classes: (*a*) the shaped or formed profile cutters and (*b*) the form or cam relieved cutters. They can also be classified as profile-ground and face-ground formed cutters, respectively, according to the method of sharpening.

(*a*) *Shaped or formed profile cutters* are sharpened by grinding a small land back of the cutting edge, as in the case of plain milling cutters, and the contour of the cutter must be reproduced every time the cutter is resharpened.

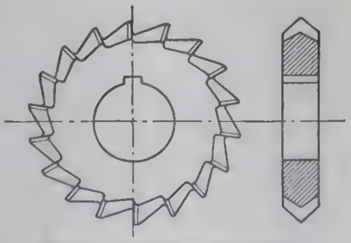

Fig. 8. Double-angle cutter.

(*b*) *Formed or cam relieved cutters* are so termed in contradistinction to shaped profile cutters because the clearance back of the cutting edge is produced by a form or master tool in a cam relieving machine, giving all the teeth the contour of the master tool. They are sharpened by grinding the face of the teeth.

So long as the face of a tooth is maintained in its original plane with respect to the axis of rotation, the contour of the tooth will remain unchanged.

This type of cutter includes gear cutters, multiple-gear cutters, sprocket cutters, convex cutters, concave cutters, corner rounding cutters, spline cutters, etc.

Formed and shaped cutters are used for the accurate duplication of varying outlines or shapes and make possible economical milling of complicated contours.

End mills (Fig. 9) are cutters with teeth on the circumferential surface and on one end. The teeth may be either parallel to the axis of rotation or helical, and either right or left hand. End mills of moderate angle commonly are called spiral end mills. End mills are made of five general types: solid end mill; two-lip end mill or slotting mill; shell end mill; hollow mill; helical end mill.

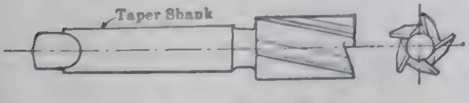

Fig. 9. End mill.

Solid end mills are used for light milling operations, as the milling of slots, profiling, and facing narrow surfaces. The teeth are integral with the shank, which may be either straight or tapered.

Two-lip end mills comprise a shank cutter with two cutting teeth on the circumferential surface and end teeth cut to the center. Flutes are either straight or helical. The cutter can be sunk into the material and then fed longitudinally. A depth of cut equal to one-half the diameter of the mill usually can be taken from the solid stock.

T-slot Cutter. A shank cutter designed for milling T slots. (See Fig. 10.) The teeth are on the circumferential surface and both sides. In making a T slot, a groove first is cut with an ordinary side milling cutter or a two-lipped end mill. The wide groove at the bottom then is cut with the T-slot cutter.

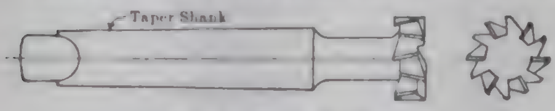

FIG. 10. T-slot cutter.

The Woodruff key seat cutter is made in the *shank* and *arbor* types. The shank type generally has teeth on the circumferential surface only, with the sides slightly relieved for clearance. The arbor type is generally used in sizes larger than 2 in. in diameter. These cutters also are made with staggered teeth. They are made with teeth on both sides which are ground for clearance only and not for cutting. Both types of cutters are used for the specific purpose of milling semi-cylindrical keyways in shafts, to permit the use of Woodruff keys.

A fly cutter consists of a single cutting tool, held and rotated by an arbor. It is used in the experimental room or tool room. The fly cutter can be formed exactly to any desired shape.

Face mill has a cylindrical body with slots on its periphery. Blades or teeth of high-speed steel are inserted in the slots. The teeth are ground to cut both on the circumferential surface and the side, as in the *side mill*. These cutters are adapted to be attached directly to the spindle nose or to the end of a stub arbor. They are made in *light-duty* and *heavy-duty* types. The *light-duty* has a lighter body and a large number of teeth, being used principally for finishing cuts. The *heavy-duty* face mill has a stronger, heavier body and fewer blades and is employed for heavy-duty roughing cuts.

Face mills are used to mill large surfaces and are highly efficient in the removal of metal.

Like face mills, almost all types of milling cutters may be made with inserted teeth. The inserted tooth cutter is most economical and useful when cutters of large dimensions are required, although they are obtainable also in diameters as low as 3 in.

Shell-end mill (Fig. 11), a face mill of the solid type with teeth cut on the circumferential surface and on one end. The tooth end is recessed to receive a nut or a screw head for holding the cutter on the stub arbor. It usually is driven from the key slot across the back face. The teeth usually are helical and either right or left hand. This type of cutter is made in sizes up to 6 in. in diameter and is used for facing operations, where a small diameter face mill would be required.

Hollow mill, a cutter of tubular construction with teeth on one end, and having an internal clearance. The internal clearance sometimes is obtained by a plain tapered hole with back taper and sometimes by internal cleared flutes. The hollow mill generally is used for producing bosses or cylindrical projections from solid bodies.

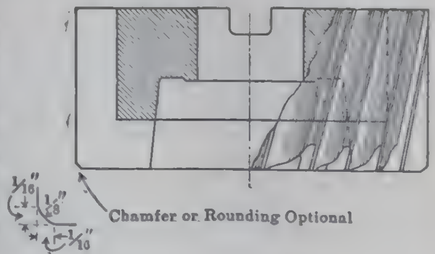

FIG. 11. Shell end mill.

CAST TOOL MATERIALS are produced by fusing various alloys at high temperature.

Cast High-Speed Steel. Milling cutters are also made of cast high-speed steel. Its characteristics lie between those of forged high-speed steel and sintered carbide. The proper physical characteristics are obtained by heat treatment.

Its hardness varies between 63 and 70 Rockwell C, depending on heat treatment. Because it has greater red hardness than forged high-speed steel, this material can be run at higher cutting speeds and is suitable for milling diversified materials.

Cast nonferrous tool materials are cast to desired shape, are fully hard after cooling at room temperature, and are finished to size by grinding. They are known under such various names as Stellite, Tantung, and Crobalt.

These materials are used as inserted blades in a variety of milling cutters, especially those of the face mill type. They are used for milling a variety of materials and can be run at higher cutting speeds than forged high-speed steel.

SINTERED CARBIDE TOOL MATERIAL is extremely hard at both room temperature and the temperature attained by the cutting edge during cutting. Cutting speeds are three to ten times as fast as with high-speed steel cutters with a comparable increase in tool life between resharpenings.

Sintered carbide is used in the form of tips, brazed to inserted blades, directly to the cutter body or bits mechanically clamped.

Made in different grades to suit operating conditions and material cut, sintered carbide consists of a mixture of powdered carbide of tungsten or of tungsten, tantalum, and titanium carbides in various combinations, with cobalt or nickel as low-melting-point cementing or binding material.

As the binder content is increased, the material becomes tougher and vice versa. Greater toughness, however, is obtained at the expense of hardness. Hardness of various grades may vary between 80 and 93 Rockwell A. Cutting fluids are not used with carbide materials.

Basic types—tungsten carbide is suitable for machining cast iron, mild steel, bronze, aluminum, magnesium, and alloys of these metals, as well as nonmetallic materials such as workable plastics, Bakelite and hard rubber. A generally used grade has 87% tungsten carbide with 13% cobalt binder. Rockwell A hardness varies between 87 and 87.5.

Tantalum carbide is used for machining carbon steels and alloy steels up to 250 Bhn. A typical composition consists of 75% tantalum carbide, 13% tungsten metal, and the remainder binder. It has a Rockwell A hardness of approximately 88.

Tungsten—titanium carbide, suitable for machining steels and alloy steels up to 500 Bhn, is predominantly tungsten carbide, with titanium carbide and 13% binder material. The Rockwell A hardness is approximately 90.

The harder grades of carbides are more wear resistant, but also display more of a tendency to chip under impact.

DIRECTION OF ROTATION. A cutter is *right-hand* if it rotates counterclockwise, and *left-hand* if it rotates clockwise, when viewed from the front end as mounted on the spindle.

NUMBER OF TEETH. Milling cutter teeth are equally spaced and project from the body of the cutter either radially as in helical mills, or both radially and axially as in face mills. The teeth may either be an integral part of the cutter or be inserted in the body in the form of inserts or blades. No standard rule exists for the number of teeth in milling cutters.

High-speed steel cutters generally are of the "coarse-tooth" type. The coarse-tooth cutter provides a great chip space between successive teeth, which permits a free flow of the chip and prevents clogging of the teeth. The efficiency of the coarse-tooth cutter is considerably higher than that of the old-style fine-tooth cutter. (See Refs. 4 and 5.) In metal-slitting saws, the number of teeth varies according to the type of operation. Coarse-tooth saws having side teeth for chip clearance, as in side mills, are used when cutting deep slots. Saws with finely pitched teeth are used for cutting thin material. Special formed saws, with teeth ground as in formed relieved cutters, are used for slitting copper and other soft nonferrous materials. Formed relieved cutters are of the coarse-tooth type to provide sufficient material for a large number of resharpenings before the cutter is used up.

Cast nonferrous tool materials cutters have approximately the same number of teeth as cutters made of high-speed steel.

Sintered Carbide-tipped Cutters. The number of teeth can be calculated for given values of feed per tooth, depth of cut, and width of cut, the object being maximum power utilization without overloading the driving motor, by means of the following formula:

$$T = \frac{KHp}{F_t N d w}$$

where T = number of teeth; K = constant, which may be taken equal to 0.650 for steel, 1.5 for cast iron, and 2.5 for aluminum. (These are conservative values which take into consideration the dulling of the cutter in service.) Hp = horsepower available at the cutter; F_t = feed per tooth, inches; N = cutter revolutions per minute; d = depth of cut, inches; and w = width of cut, inches.

In general, the number of teeth in a milling cutter should be selected on the basis of all-round good performance. The following rule has been found to give satisfactory cutter performance, strong tooth section, ample chip space, economy in cost and maintenance, and good cutting efficiency, and yet assure a continuous cutting action:

> Provide the cutter with a number of teeth so that no more than two teeth are engaged in the cut at any time.

On this basis, the following formula can be used for obtaining the number of teeth in **face milling cutters:**

$$T = \frac{\pi D n}{w}$$

where T = number of teeth; D = cutter diameter, inches; n = number of teeth in contact; and w = width of cut, inches.

For peripheral milling cutter:

$$T = \frac{4\pi D}{D + 4d} \cos a$$

where T = number of teeth; D = cutter diameter, inches; d = depth of cut; and a = helix angle, degrees.

21. OPERATION OF MILLING CUTTERS

CUTTING SPEED. Because of the countless variations in conditions encountered in milling practice, fixed rules for cutting speeds are impossible. The most effective speeds are governed by the structure and hardness of the part to be machined, the amount of metal to be removed, the type of cutting material, etc. In general, cutting speed is selected to give the best compromise between maximum production and maximum life of the cutter.

Approximate values of the cutting speed for different cutting materials, based on the Brinell hardness number or tensile strength of the material being cut, are obtained from Figs. 12, 13, and 14.

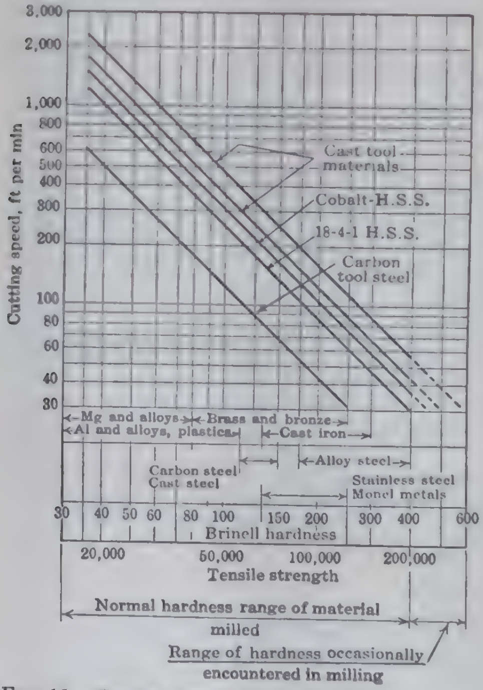

FIG. 12. Cutting speeds for different cutting tool and work materials.

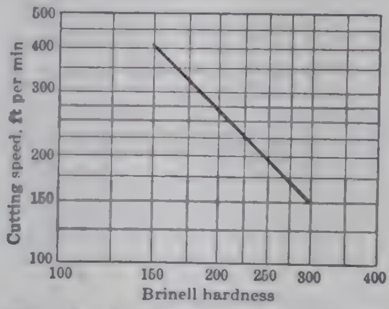

FIG. 13. Cutting speeds in milling cast iron with carbide-tipped cutters.

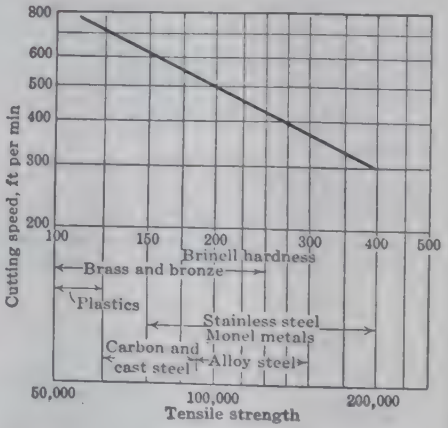

FIG. 14. Cutting speeds for milling steel with carbide-tipped cutters.

In milling with sintered carbide-tipped cutters, there is considerable variation in the cutting speed according to the grade of carbide used, the cutter design, the material being cut, and the nature of the operation.

The selected cutting speed may have to be adjusted in the actual operation to provide satisfactory cutter life, good finish of the milled surface, and operation of the machine within the power available in the driving motor.

Magnesium and aluminum alloys are milled with sintered carbide-tipped cutters within a wide range of cutting speeds. Cutting speeds of 3500 to 12000 ft per min and higher have been used when milling these materials. In general, the selection of the cutting speed is determined by practical consideration, such as the nature of the work, the setup of the machine; and the spindle bearing design and the power available in the machine.

The cutting speed for finishing milling often is 40 to 80% higher than the roughing speed.

FEED RATE. The rate of production in milling depends directly on the rate at which the work passes the cutter. This value in inches per minute may be computed from

$$F = F_t T N \tag{1}$$

where F_t is the feed per tooth, T the number of teeth, and N the rpm of the cutter. Selection of the proper feed rate for milling a given work piece involves several factors, among them the limitations of machine, cutter, work piece, and fixture; the finish desired, etc.

Estimates of feed rates usually are based on the assumption of a certain value of F_t, the feed per tooth.

In practice the feed per tooth is made as large as possible, consistent with these limitations and the permissible tooth load. Tables 1 and 2 give average values of permissible feed per tooth for various combinations of work material and types of milling cutters for high-speed steel and sintered carbide-cutting materials. For cast nonferrous tool materials the values of the feed per tooth are the same as those for sintered carbide. These values must be reduced when cutter, or work, is of a relatively fragile nature.

DIAMETER OF CUTTER usually is determined by the limitations of the work piece, either in regard to the size of the surface to be milled or interference with adjacent portions of work or fixture. In the case of cutters of small diameters, the limitation frequently is the size of the arbor required to support it properly.

CLEARANCE ANGLE (Relief). The clearance angle is that angle included between the land on the back or flank by a milling cutter tooth, and the tangent to the periphery of the cutter at the cutting edge. Its sole function is to prevent undue interference between the land and the surface being generated on the work piece by the cutting edge.

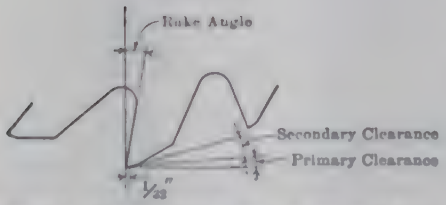

Fig. 15. Clearance and rake angles, and land.

As shown in Fig. 15, the clearance angle is sometimes referred to as the *primary clearance*, since a *secondary clearance* is usually provided when sharpening cutters to restore the keenness of the cutting edge.

The clearance angle should be carefully selected in all types of cutters. The value of the clearance angle plays an important role in obtaining good cutter performance, high cutting efficiency, good finish, and long cutter life. Any clearance greater than the minimum amount required increases the likelihood of chatter and reduces the life of the tool.

For general-purpose work, milling cutters $\frac{1}{8}$ to 3 in. in diameter have clearance angles of 13 to 5 degrees, respectively, decreasing proportionately as the diameter increases. In cutters over 3 in. in diameter, cutter manufacturers usually provide a clearance of 5 degrees.

The land is usually about $\frac{1}{64}$, $\frac{1}{32}$, and $\frac{1}{16}$ in. wide in cutters of small, medium, and large diameter, respectively.

The value of the clearance angle is also changed according to the material of the work piece. Generally used values are given in Table 3.

Table 3. Milling Cutter Clearance Angles for Various Work Materials

(The Cincinnati Milling Machine Co.)

Material to Be Cut	Clearance Angle, degrees
Low-carbon steel	3– 5
High-carbon and alloy steels	3– 5
Cast iron	4– 7
Medium and hard bronze	4– 7
Brass and soft bronze	10–12
Aluminum, magnesium, plastics, etc.	10–12

RAKE ANGLE. In *peripheral milling cutters*, the rake angle or "undercut" is generally defined as the angle in degrees measuring the deviation of the tooth face from a radial line to the cutting edge. This is the radial rake angle (Fig. 15).

In *face milling cutters*, the teeth are inclined with respect to both the radial and axial lines (Fig. 16). These angles are called *radial* and *axial rake*, respectively.

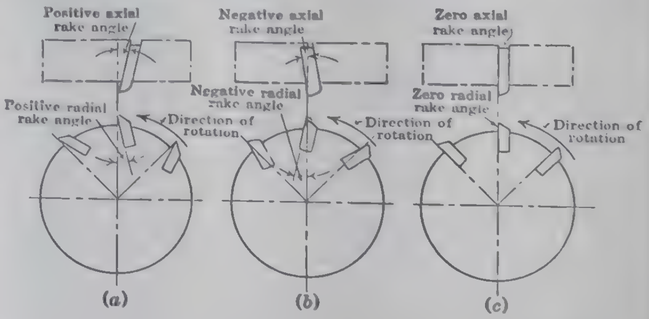

Fig. 16. Radial and axial rake angles in face milling cutters.

The rake angles may be *positive*, *zero*, or *negative*.

Selection of Rake Angles. *High-speed Steel.* Positive rake angles should be used in all types of high-speed steel milling cutters. Angles of 10 to 15 degrees are used for milling steels of various compositions. For softer materials such as aluminum and magnesium, the rake angle may be increased to 25 degrees or more.

In special milling cutters, the rake angle is selected to suit the particular operation.

Metal slitting saws have rake angle of 5 to 10 degrees. Zero and sometimes slightly negative rake angles are used in saws operating on copper or other soft nonferrous metals to counteract the tendency to "hog in."

In standard *formed relieved* cutters, the rake angle may be 10, 5, or zero degrees.

Face milling cutters usually have 10-degree positive radial and axial rake angles, for milling cast iron, steels, and nonferrous metals such as bronze and brass. It may be increased to 25 degrees or more when milling aluminum and magnesium. Rake angles for face milling cutters are given in Table 4.

Table 4. Face Milling Cutter Rake Angles for Various Cutting Materials and Work Materials

(The Cincinnati Milling Machine Co.)

Material Cut	Cutter Material			
	High-speed Steel		Cast Nonferrous Tool Material	
	Radial Rake, degrees	Axial Rake, degrees	Radial Rake, degrees	Axial Rake, degrees
Soft cast iron	10–15	10–15	6–8	6–8
Mild steel	10–15	10–15	3–6	3–6
Hard cast iron	10	10	3–6	3–6
Hard alloy steel	10	10	0–3	0–3
Aluminum and alloys	20–35	20–35	10–15	10–15
Magnesium and alloys	20–35	20–35	15–25	15–25
Yellow brass and bronze	10	10	5	5

CAST NONFERROUS TOOL MATERIALS. Positive rake angles are generally provided on milling cutters using cast nonferrous tool materials. Negative rakes may be employed for some operations where shock loads are encountered or when it is necessary to eliminate vibration when milling thin sections. Values of rake angles for face milling cutters are given in Table 4.

Sintered Carbide. *Face Mills.* Recent developments in the design of carbide-tipped face mills have indicated five principal angles which control cutting performance: (1) axial rake, (2) radial rake, (3) true rake, (4) inclination, and (5) corner angle. These angles are shown in Fig. 17. (See Ref. 6.)

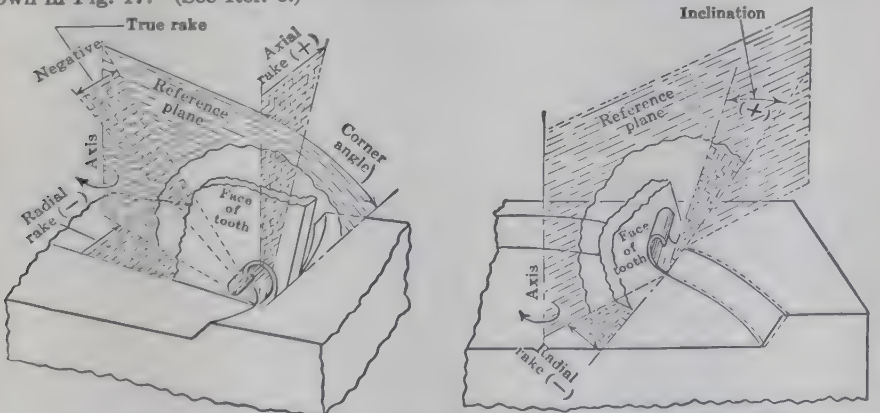

Fig. 17. Angles which control cutting performance of carbide-tipped face mills.

The *true* rake determines tool life, surface finish, power consumption, and machine deflection. For long tool life, a *negative true rake* should be used. To eliminate chip crowding by directing them away from the cutter body, a *positive inclination* should be used. A number of rake-angle combinations can be used to obtain desirable results (see Fig. 18).

A desirable chip flow is obtained by using *positive axial rakes* in combination with *negative radial rakes* and *large corner angles*.

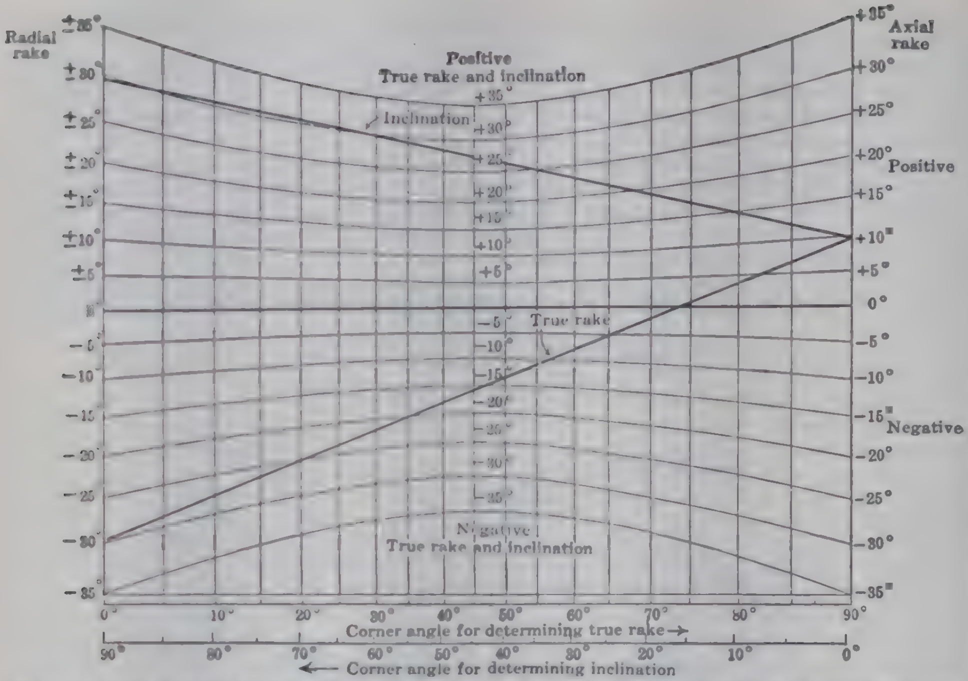

FIG. 18. True rake and inclination of face milling cutter teeth. On left-hand scale use upper sign for true rake, lower sign for inclination.

Milling Cutter Angles for General-purpose Milling of Steel. *Face mills* should have a *negative true rake*, a positive inclination, and a corner angle of at least 45 degrees. The value of the negative true rake should increase with the hardness of the steel. Combinations which have proved satisfactory in practice are given in Table 5. Where the cutting conditions are extremely severe, because of hard inclusion or chip crowding, true negative rakes as high as 25 degrees may be used. When high feed rates can be used, it is advantageous to increase the corner angle to as high as 75 degrees.

Table 5. Face Mills
Recommended Rake Angles for Steel
(The Cincinnati Milling Machine Co.)

		Axial Rake	Radial Rake	Corner	True Rake	Inclination
Face Milling	Low-carbon and Annealed Alloy Steels	+5	−12	45	−5	+12
	Hardened Alloy Steels	+5	−18	45	−10	+16

Slab Milling, Slotting, and Sawing. Satisfactory combinations of tooth angles are given in Table 6.

Table 6. Tooth Angles Combinations for Slab Milling, Slotting, and Sawing
(The Cincinnati Milling Machine Co.)

		Axial Rake	Radial Rake	True Rake
Slab Milling	Low-carbon and Annealed Alloy Steels	5	−5	−5
	Hardened Alloy Steels	10	−10	−10
Slotting and Sawing	Low-carbon and Annealed Alloy Steels	0	−5	−5
	Hardened Alloy Steels	0	−10	−10

A general grade of sintered carbide for milling steel is represented by Carboloy 78-B, Kennametal KM, Vas-Ramet EM, and Firthite TA.

Softer and harder grades can be obtained. The harder grades are more wear-resistant but also have a tendency to chip under impact or vibration.

Milling Cutter Angles for General-Purpose Milling of Cast Iron. Face mill tooth angles vary over a wide range. Values of true rakes for any combination of axial rake, radial rake, and corner angle may be obtained from Fig. 18. For average conditions, the true positive rake should vary from 4 to 10 degrees. Corner angles, from 30 to 45 degrees. A face mill which allows high feed rates and minimizes break out of work piece at the edge where cutter leaves the work has corner angles of 60 to 75 degrees. One combination of angles that has proved satisfactory is: Axial rake +15°; Radial rake −30°; corner angle 75°; true rake 6°; inclination +32°.

A general grade of sintered carbide for milling cast iron is Carboloy 44A, Kennametal K6, Vas-Ramet 2468, and Firthite H.

Milling Cutter Angles for Milling Light Alloys. For aluminum and magnesium alloys, positive rake angles are generally used, ranging from 10 to 20 degrees for aluminum and 15 to 25 degrees for magnesium.

Flywheels. In all carbide applications it is now the practice to use flywheels mounted as close as possible to the milling cutter to avoid tip breakage due to vibrations.

CUTTING FLUIDS play an important role in the majority of metal-cutting operations. They are almost invariably used in milling operations on steel, alloy steel, brass, and bronzes with high-speed steel cutters. Aluminum and magnesium alloys and cast iron are mostly milled dry, although cutting fluids are used in some particular cases.

With sintered carbide-tipped cutters, cutting fluids are generally not used.

Compressed air or a rotating wire brush is useful in removing the chips off the cutter. In milling aluminum and magnesium an abundant supply of cutting fluid is used to wash away the chips.

In addition to reducing the temperature of cutting, cutting fluids prevent adhesion between the chip and the cutter teeth and improve the quality of finish.

The cutting fluids most generally used may be grouped as follows:

1. Emulsions of water and other elements such as waxes, mineral oil containing soap or sulfur, and pastes, with added antirust compounds.
2. Cutting oils, which may be straight mineral oils, animal and vegetable oils, or compounded oils having a sulfurized or sulfurized-chlorinated base.
3. Air supplied in the form of a jet.

In order to be of practical value in the shop, a cutting fluid should have certain desirable characteristics:

1. It should have a high cooling capacity to reduce cutting temperature, increase cutter life and production, and improve dimensional accuracy.
2. It should prevent adhesion between the material of the chip and the cutter teeth to improve chip formation and surface finish.
3. It should be suitable for a variety of milling operations on different work materials to be cut, thus reducing the number of cutting fluids used in the shop.
4. It should have long life and should not emit obnoxious odors or vapors harmful to the operator.
5. It should not cause rust or corrosion.
6. It should have low viscosity, to permit gravity separation of impurities and chips collected by the fluid as it is circulated in the cooling system.
7. It should not oxidize or form gummy deposits to clog the circulating system and thus halt production while the system is cleaned.
8. It should permit a clear view of the work, which is especially desirable in precision work.
9. It should be safe, particularly in regard to fire and accident hazards.
10. It should not cause skin irritation.

Of the variety of cutting fluids available, water emulsions may be prepared to possess most of the desirable properties that a cutting fluid should have, and accordingly are used in milling operations.

COMPARISON OF UP-MILLING AND DOWN-MILLING. At various times during the past 50 years down-milling (or milling with the feed) has been advocated for particular classes of work, in view of certain advantages inherent in this method. In recent years this method has been used with special types of feed systems, designed to prevent an overrunning of the milling machine table due to the action of the cutter on the work.

When thin metal slitting cutters are used, the likelihood of producing crooked slots is less when milling down than when milling up. In milling the flutes in twist drills, and other similar operations, a longer tool life and more desirable finish have been obtained when milling down, and the holding of the work piece during the milling operation is greatly simplified. In carbide applications, the down-milling method should be used wherever possible. The greatest practical objection to the down-milling method for heavy milling work is the danger of a serious accident if the work piece or fixture should be insecurely fastened to the table.

From the standpoint of power required, there is little to choose between the two methods of milling. Careful tests have shown in most cases that there is very little difference between the power actually used by the cutter when removing chips by either up-milling or down-milling.

POWER REQUIRED FOR MILLING is a function of many factors, including the cutting speed, the feed, the material being cut, the rake angle, the sharpness of the cutter, the depth of cut, the smoothness of the face of the teeth, and the type of cutting fluid used.

An empirical formula that can be used for an approximate determination of the power required in milling is

$$\mathrm{Hp} = aV^{3/4} \qquad (2)$$

where Hp = horsepower actually used in cutting; a = a constant which is different for different materials, values being given in Table 7; V = rate of stock removal, cubic inches per minute, equal to

$$V = FWD \qquad (3)$$

where F = feed rate, W = width of cut; and D = depth of cut. The power required can also be evaluated from Fig. 19.

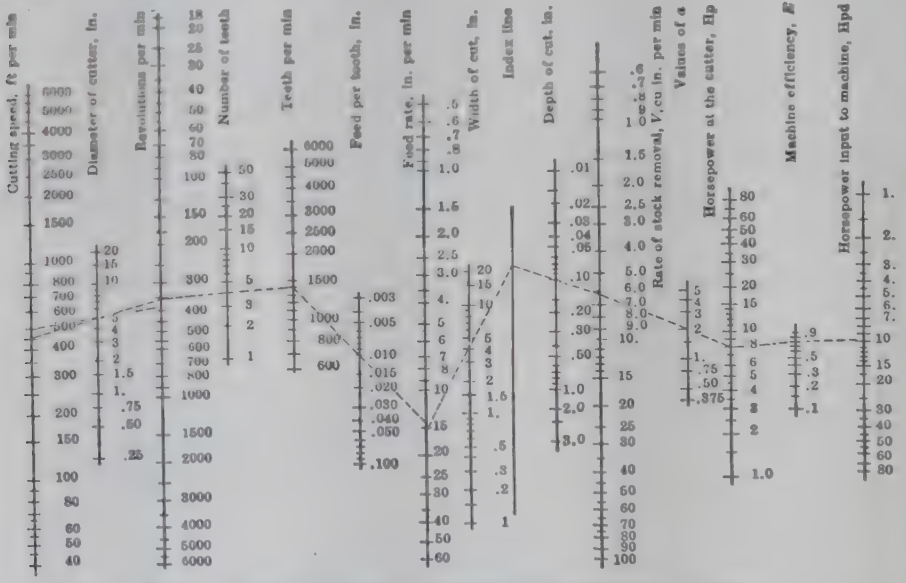

FIG. 19. Alignment chart for calculating power required in milling.

In order to obtain the total actual power required to perform a milling operation in any given type of milling machine, it is necessary to add to the result of calculation by eq. 2, the idle power required to drive the machine. Idle power varies in relation to the type of milling machine used. However, it generally is found that the idle power is approximately constant within the range of loads encountered in ordinary milling machine operation.

TYPICAL MILLING JOBS. SPEEDS. FEEDS. The following are representative examples of good commercial practice:

Automotive Practice. (1) Rough mill cylinder blocks, top and bottom, manifold, bearing cap slots, and valve cover pads, using Stellite tools: Cutting speed, 110 ft per min; feed, 10.5 in. per min; depth of cut, $^1/_8$ in.; production, 13.6 pieces per hr; pieces per grind, 200.

(2) Mill clutch housing on cylinder blocks, using cemented carbide tools: Cutting speed, 250 ft per min; feed, 12 $^1/_2$ in. per min; depth of cut, $^1/_{32}$ in.; production, 60 pieces per hr; pieces per grind, 6720.

		1	Shell end mill	2 1/4	High-speed steel	111	66	8	0.0072	1/8

(3) Finish-mill rear end of cylinder blocks, using cemented carbide tools: Cutting speed 250 ft per min; feed, 16 in. per min; depth of cut, 0.015 in.; production, 44 pieces per hr; pieces per grind, 3168.

(4) Mill mounting pads of master cylinder body, using Stellite cutters: Cutting speed, 140 ft per min. feed, 11 $^{1}/_{4}$ in. per min; depth of cut, $^{1}/_{8}$ in.; production, 130 pieces per hr.

(5) Mill bosses on shock absorber body, using Stellite cutters: Cutting speed, 128 ft per min; feed, 25 in. per min; depth of cut, $^{3}/_{16}$ in.

Table 8 gives data concerning the milling operations on a 12-cylinder automobile motor block.

General Practice. (1) Bottle mold halves; mill parting faces and tongue, using tungsten carbide and high-speed steel cutters. Material, cast iron; cutting speed, tungsten carbide cutters, 170 ft per min; high-speed steel cutters, 53 ft per min; feed rate, tungsten carbide cutters, 9 $^{7}/_{8}$ in. per min, high-speed steel cutters, 3 $^{5}/_{8}$ in.; depth of cut, $^{1}/_{16}$ in.

(2) Roller-spider; mill three cams using high-speed form cutter: Material, steel forging; cutting speed, 78 ft per min. feed variable, average, 5 $^{1}/_{2}$ in. per min; depth of cut, $^{1}/_{16}$ in.; time per piece, 1.22 min; production, 42 pieces per hr.

(3) Transmission case, mill face, using high-speed steel cutters: Material, cast iron; cutting speed, 60 ft per min. feed, 5 in. per min; production, 8 pieces per hr.

(4) Compressor cylinder. Material, SAE 1112 steel; high-speed steel slotting cutter: cutting speed, 64 ft per min; feed, 5 $^{3}/_{8}$ in. per min; depth of cut, 0.025 in.; production, 229 pieces per hr.

(5) Master cylinder body; mill mounting pads, using Stellite face mill cutter: Material, cast iron, cutting speed, 140 ft per min; table feed, 11 $^{1}/_{4}$ in. per min; production, 130 pieces per hr.

(6) Block plunger feed trip; mill slot and angle using a gang of high-speed steel cutters: Material, SAE 1112 steel; cutting speed, 65 ft per min; feed rate, 2.4 in. per min; depth of cut, 1 $^{1}/_{2}$ in.; production, 12 pieces per hr.

(7) Fork; mill inside and outside of fork; mill radius and end, form-mill other radius and end. Material, steel casting; 1st and 2nd operation: Use gang of four high-speed steel cutters; cutting speed, 55 ft per min; feed rate, 5 $^{3}/_{8}$ in. per min; depth of cut, $^{1}/_{8}$ in. 3rd operation: Use high-speed steel form cutter; cutting speed, 50 ft per min; feed rate, 3 in. per min; depth of cut, $^{1}/_{8}$ in.; production, 6 pieces per hr.

(8) Bracket; mill bottom and inside edges using high-speed steel face mill cutter and high-speed steel end mill: Material, cast iron; cutting speed, roughing, 80 ft per min; finishing, 120 ft per min; feed rate, roughing, 11 $^{3}/_{4}$ in. per min; finishing, 9 $^{1}/_{4}$ in. per min; depth of cut, $^{3}/_{16}$ in.; production, 2 pieces per hr.

22. MILLING AND MILLING MACHINES

MILLING. Application of milling, in relation to the number of parts being manufactured, may be broadly classified as: *toolroom milling* and *production milling*.

Toolroom milling refers specifically to milling operations performed on one or a few parts only, such as may be needed for experimental or development work and for repairs. Jobbing shop work is also included in this category. The parts to be milled are located and held on the machine table in temporary setups, utilizing standard attachments, commercial or home-made clamping, and locating devices because changes in setup are frequent. For this reason, milling equipment must be flexible to permit quickly changing the setup to accommodate different parts.

Production milling is characterized as small lots or large-quantity production, depending on the number of identical parts processed through a shop at any given time. The objectives are low production cost and interchangeability of parts.

Parts are usually located and held in fixtures clamped to the machine table. The fixtures may be especially designed for locating and clamping a specific part, or, by means of removable units, may be adapted to locate and clamp a series of different parts. The milling equipment, once set up, will operate on the same job for long periods of time and, for this reason, is not as flexible as that used in toolroom milling.

Fully automatic operation of the equipment may be necessary to achieve a high production rate per hour. The production rate is determined as follows:

$$P = \frac{60E}{t}$$

where P = production per hour, number of pieces; t = time per piece, minutes; E = efficiency of use of the equipment, usually ranging from 80 to 85%, depending upon shop conditions.

For efficient production milling a thorough study must be made of the requirements of the job as to rate of production, accuracy and finish of the milled parts, the material to be milled, the method of holding and locating the parts in the fixture, the type and material of the milling cutters, the type of fixture, the type of milling machine, whether standard, special or semispecial, and the method of milling, that is, the method of arranging the parts on the machine to achieve maximum reduction in time per piece and, consequently, a maximum gain in production rate.

Methods. Typical methods of milling are:

Single piece. One piece or part is milled per machine cycle. Machine is idle to allow operator to load and unload the fixture. This method is generally used when milling medium-large-size parts.

String milling. A number of parts are placed, like beads on a string, along the machine table. Part of the loading and unloading time is saved. This method is used when milling small-size parts.

Reciprocal milling. The parts are arranged on opposite sides of the cutter. Loading and unloading take place on one end of the table, while the parts on the other end of the table are being milled, thus saving loading and unloading time. This method is used for small to medium-size parts.

Abreast milling. This is a method in which two or more parts are milled simultaneously. They are located side by side along the table width. Milling time is reduced in relation to the number of parts abreast. This method is also used for milling medium and small-size parts.

Transfer base milling. Parts are located on an index base having two, four, or more stations. The parts in each station are milled in sequence. Loading and unloading of parts in the other station take place while milling the parts in one station. This method is similar to reciprocal milling and avoids the operator's having to walk from one end of machine to the other. It is used for medium and small-size parts.

Rotary milling. The parts are arranged on a continuously rotating table, which continuously presents parts to be milled to the cutter, while the operator loads and unloads the fixture not in use. This method provides maximum utilization of the equipment, since the time per cycle is milling time.

The foregoing methods are usually combined, depending upon the application.

MACHINE CLASSIFICATION AND USES. The types and sizes of milling machines are numerous, and their designs merge into one another. It is, therefore, difficult to classify them. The following classification is based on general appearance or design.

(1) **Knee and column type** is so called because the spindle is fixed in the column or main body; the table is capable of manual adjustment and power feed and rapid traverse rates of movement longitudinally, transversely, and vertically. By set trip dogs the table can be operated through an automatic cycle of feed and rapid traverse in both directions of movement. Machines of this type are of rather universal application and generally are selected for that class of production milling that involves medium and small parts, processed in limited quantities, with frequent setups. They are especially used in toolroom, jobbing shops, and experimental laboratory work.

These machines can be equipped with fixtures and multispindle attachments to permit their use as production units. Such procedure pays in many shops, where certain jobs are manufactured in sufficient quantities to justify a knee and column type machine for high production, with the idea that it can easily be stripped of its high-production elements and put back on regular run of work.

Knee and column machines are subdivided as follows: (1) *Plain horizontal*, with spindle located horizontally, using facing and peripheral milling cutters; (2) *universal*, equipped with a swiveling table, for the cutting of helical grooves; and (3) *vertical*, with spindle located vertically, using chiefly face milling cutters.

(2) **Hand millers** usually are small machines of the knee and column type, in which the feeding movement of the table is controlled by hand. They are used in the manufacture of comparatively small quantities of light parts. Hand millers are subdivided into (*a*) floor type and (*b*) bench type. The latter are used for the machining operations of very light work.

(3) **Fixed bed type** machines are intended for use in the manufacture of parts in large quantities, and for this reason they are more rigidly built and simpler than the knee and column type millers. These machines are built on the plan of standard unit construction, which permits the make-up, from standard and complementary units, of a great variety of spindle combinations and feed cycles to meet the specific requirements of manufacture of a given product. (See Figs. 20 to 27.)

Fixed bed machines, with proper fixtures to clamp the work, operate on definite automatic cycles, such as rapid advance of work to cutter, cutting feed, rapid return to the starting position, and stop. These machines are subdivided into plain (single spindle); duplex; multiple spindle; rail; bridge; special types.

(4) **Rotary and drum type millers** are provided with fixtures and are used for mass-production work in which the cutting is continuous, with no idle time. The parts are loaded on one side of the machine. They pass first the roughing, and then the finishing cutters, and return to the loading position, where they are replaced. Drum type machines derive their name from the fact that the parts to be milled are mounted on a drum-like table that rotates continuously.

FIGURES 20 to 27. Milling operations on automotive cylinder blocks and heads. See Table 8.

(5) **Planetary milling machines** are used to mill plain or formed internal surfaces. The cutter is inserted in the bore to be milled and, while rotating, is fed to depth radially, makes a single sweeping cut about the bore.

(6) **Thread milling machines** are designed to cut threads and worms, using properly designed milling cutters.

(7) **Die-sinking and profiling machines** are designed to reproduce accurately complicated forms and contours from a master by means of a tracer, contact with which is maintained by the master form throughout the operation, thus controlling the position of work and cutter. These machines are subdivided into: (*a*) Hand controlled, in which the tracer is guided by hand over the master form. (*b*) Automatic, where the tracer, once the cycle is started, follows automatically the master form without requiring the assistance of the operator.

MILLING MACHINE ATTACHMENTS. The range of work that a milling machine can do is greatly increased by the use of attachments, of an almost endless variety to satisfy special requirements. Many of these attachments have now become standard units. Among these the most important are (1) universal dividing head; (2) index head; (3) heavy vertical milling attachment; (4) circular milling attachment; (5) universal spiral milling attachment; (6) slotting attachment; (7) rack milling attachment; (8) transfer or index base; (9) cam milling attachment; (10) toolmaker's vise; (11) vertical milling attachment with automatic depth control, for die sinking.

DRILLS AND DRILLING

By C. J. Oxford

23. TWIST DRILLS

DEFINITION. Twist drills are end cutting tools having one or more cutting edges, and having helical grooves adjacent thereto for the passage of chips and for admitting coolant to the cutting edges. Twist drills are used either for originating holes or for enlarging existing holes.

NOMENCLATURE. The nomenclature shown in Fig. 1 has been adopted by the American Standards Association.

Twist drills are manufactured with either straight or taper shanks as indicated in Fig. 1. Drills smaller than $^1/_8$ in. in diameter are made with straight shank only. Drills $^1/_8$ in. in

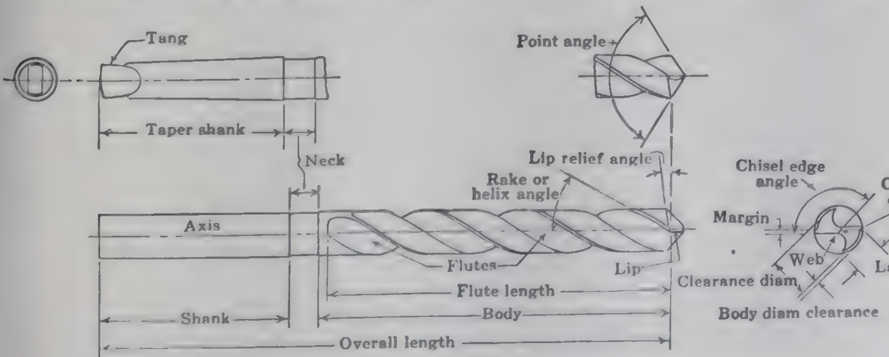

FIG. 1. Twist drill nomenclature.

diameter and larger are made with either straight or taper shanks in the fractional series (see next paragraph). Taper shank drills are made with Morse taper. For dimensions of Morse tapers, see p. 18-19.

TWIST-DRILL PROPORTIONS. Twist drills are manufactured and listed by the makers in three separate series of diameters. They are the fractional series, the wire gage series, and the letter size series. Table 1 combines all these series in order of drill diameters.

The table also shows the respective overall and flute lengths of the various series. Fractional series drills are made in two separate lengths for drills $^1/_8$ in. in diameter and larger, as shown in the table.

SPECIAL DRILLS. In addition to the general-purpose drills described in the foregoing, many special designs of drills are used for definite applications and for special materials to be drilled. Some are available from manufacturers' stocks in the listed diameters and lengths. Others must be designed and manufactured to suit a particular application or material. Figure 2 shows a drill designed for use when drilling deep holes in

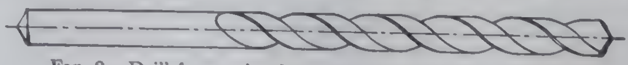

FIG. 2. Drill for use in aluminum, magnesium, slate, etc.

aluminum and magnesium alloys and for drilling holes in slate and some plastic materials used for electrical switchboard panels.

Figure 3 shows a heavy-duty type of drill used extensively for drilling interrupted holes in hard and tough steels. Drilling of cross holes for cotter pins is a good example of the use of this type of drill.

FIG. 3. Heavy-duty drill for interrupted holes in hard, tough steel.

Figure 4 shows a low helix drill much used for drilling brass, and for horizontal drilling of brass and soft steel in automatic screw machines.

FIG. 4. Low-helix drill for brass, and for horizontal drilling in automatic screw machines.

Figure 5 is a drill design used for drilling molded plastics, hard rubber, wood, and some types of aluminum and magnesium alloys.

FIG. 5. Drill suitable for molded plastics, hard rubber, wood, and some aluminum and magnesium alloys.

For drilling exceptionally deep holes in steel, such as oil holes in automotive crankshafts and connecting rods, the type of drill shown in Fig. 6 finds wide use. A large helix angle and very heavy web are characteristic of this type of drill. Special sharpening is necessary to make such drills perform to best advantage. The split point or so-called "crankshaft point" illustrated in Fig. 7 is found most satisfactory for this purpose.

FIG. 6. Drill for deep holes in steel.

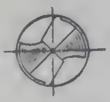

FIG. 7. Split point for drill in Fig. 6.

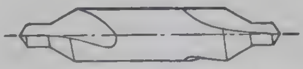

FIG. 8. Combined drill and countersink.

Other types of drills that find wide use in industry are three-flute and four-flute drills used for enlarging existing holes, and the combined drill and countersink shown in Fig. 8. The last is used extensively for producing center holes in lathe work.

24. DRILLING PRACTICE

SPEEDS FOR DRILLING. The varying conditions under which drills are called upon to operate, as well as the wide variety of materials, having different characteristics, to be drilled, make it impracticeable to lay down any hard and fast rules for drill speeds. In general it may be stated that permissible speeds depend on the hardness and the toughness of the material to be drilled. The harder or tougher the material, the lower the speed should be. Conversely, the softer the material, the higher the speed.

When using high-speed steel drills the figures given in Table 2 may be used as a convenient starting guide. Observation of the behavior of drills when so operated indicates if these speeds can be increased or if they must be decreased. If drills operate easily and without undue signs of heating, higher speeds should be tried. If, on the other hand, drills show signs of overheating, or if corners wear away rapidly, it is an indication that speeds are too high.

Carbon-steel drills should be operated at approximately 40 to 50% of the speeds given in Table 2.

Table 2. Recommended Drilling Speeds for Various Materials with High-speed Steel Drills

(Courtesy National Twist Drill & Tool Co.)

Material	Recommended Speed Surface ft per min
Aluminum and its alloys	200–300
Bakelite	100–150
Brass and bronze, soft	200–300
Bronze, high tensile	70–100
Cast iron, soft	100–150
Cast iron, hard	70–100
Magnesium and its alloys	250–400
Malleable iron	80–90
Nickel and Monel metal	40–60
Slate, marble, and stone	15–25
Steel, forgings	50–60
Steel, manganese (15% Mn)	15–25
Steel, soft	80–110
Steel, stainless	30–40
Steel, tool	50–60
Wrought iron	50–60
Wood	300–400

Drill speeds are commonly designated as peripheral or surface speed in feet per minute (sfpm). Convenient formulas for converting revolutions per minute (rpm) into sfpm or vice versa are

$$\text{sfpm} = \frac{\text{rpm} \times d \times 3.1416}{12} \quad \text{or} \quad \text{rpm} = \frac{\text{sfpm} \times 12}{d \times 3.1416}$$

where d is the diameter of drill in inches.

FEEDS FOR DRILLING. Feeds per revolution of drills do not bear the same relation to hardness or toughness of materials to be drilled as speeds. For a great majority of drilling operations it is desirable to keep the feed per revolution for a given diameter of drill approximately constant, regardless of the material to be drilled. Table 3 shows the recommended feed per revolution for various diameters of drills.

Table 3. Recommended Feeds for Drills of Various Diameters

(Courtesy National Twist Drill & Tool Co.)

Diameter of Drill, in.	Feed, in. per rev
Under $1/8$	0.001 to 0.002
$1/8$ to $1/4$	0.002 to 0.004
$1/4$ to $1/2$	0.004 to 0.007
$1/2$ to 1	0.007 to 0.015
1 in. and over	0.015 to 0.025

The formula for computing rate of penetration in inches per minute (ipm) for a given feed per revolution (fr) is

$$\text{ipm} = \text{rpm} \times \text{fr}$$

CUTTING FLUIDS FOR DRILLING. Cutting fluids serve a two-fold purpose in drilling: (1) as a coolant; (2) as a lubricant.

Table 4. Recommended Cutting Fluids for Various Materials

(Courtesy National Twist Drill and Tool Co.)

Aluminum and its alloys	Kerosene, kerosene and lard oil, soluble oil
Bakelite	Dry
Brass, soft	Dry, soluble oil, kerosene and lard oil
Bronze, high tensile	Soluble oil, lard oil, mineral oil, dry
Cast iron	Dry, air jet, soluble oil
Copper	Soluble oil, dry, mineral lard oil, kerosene
Magnesium	Low-viscosity neutral oils
Malleable iron	Dry, soda water
Monel metal	Lard oil, soluble oil
Slate	Dry
Steel, forging	Soluble oil, sulfurized oil, mineral lard oil
Steel, manganese	Soluble oil, sulfurized oil, mineral lard oil
Steel, soft	Soluble oil, mineral lard oil, sulfurized oil, lard oil
Steel, stainless	Sulfurized mineral oil, soluble oil
Steel, tool	Soluble oil, mineral lard oil, sulfurized oil
Wrought iron	Soluble oil, mineral lard oil, sulfurized oil

In production work cooling of both drill and work is usually the most important factor to consider. The amount of heat generated is so great that tool life depends on the ability of the cutting fluid to carry away the heat at approximately the same rate it is generated. For that reason lubrication must often be subordinated to cooling.

Some lubrication is desirable, particularly when drilling steel, as it will help to prevent chips from sticking at the cutting edges of the drill and so cause clogging in the flutes. Cutting fluids should be selected on the basis of their heat-dissipating or lubricating qualities as conditions demand.

The recommendations in Table 4 for cutting fluids and other media, when drilling various materials, have been found to give generally good results.

DRILL SHARPENING. It has been estimated that 90% of drilling troubles can be traced to improper sharpening. Therefore, it is highly important that care be taken when resharpening drills. A good drill point will have: (1) Both lips at the same angle with the axis of the drill. (2) Both lips of the same length. (3) Correct lip clearance angles for the material to be drilled. (4) Correct web thickness.

For drilling hard or tough steels, the point angle *C* (Fig. 9) should be 135 degrees. For drilling soft materials and for general purposes, this angle should be 118 degrees. Drills for cast iron are often sharpened with a point angle of 60 to 90 degrees. Plastics are drilled successfully with drills sharpened with a 60-degree point angle.

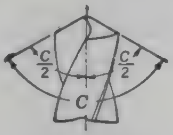

FIG. 9. Drill point angle.

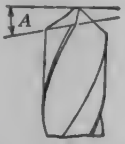

FIG. 10. Lip clearance angle.

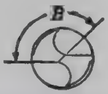

FIG. 11. Chisel-edge angle.

The lip-clearance angle *A* (Fig. 10) should be as follows. When drilling steel this angle should be 6 to 9 degrees. When drilling soft cast iron and other soft materials, *A* should be made from 12 to 15 degrees at the periphery of the drill. These clearance angles should increase toward the center of the drill so as to produce the proper chisel-edge angle *B* (Fig. 11).

The proper combination of lip-clearance angles and chisel-edge angles is as follows. When angle *A* is made 12 to 15 degrees for softer materials, angle *B* should be made approximately 135 degrees. When angle *A* is made 6 to 9 degrees for harder materials, angle *B* should be made 115 to 125 degrees.

CAUSES OF FAILURES OF DRILLS. Manufacturers of twist drills have issued to users the following instructions to aid them in analyzing troubles that may develop when drilling.

Causes of Failures of Twist Drills

Indications	Causes
Outer corners break down	Cutting speed too high. Hard spots in material. No cutting compound at drill point.
Cutting edges chip	Too much feed. Lip clearance too great.
Checks or cracks in cutting edges	Overheated or too quickly cooled while sharpening or drilling.
Margin chips	Oversize jig bushing.
Drill breaks	Point improperly ground. Feed too heavy. Spring or back lash in drill press, fixture, or work. Drill is dull. Flutes clogged with chips.
Tang breaks	Imperfect fit between taper shank and socket caused by dirt or chips, or burred or badly worn sockets.
Drill breaks when drilling brass or wood	Flutes clogged with chips. Improper type drill.
Drill splits up center	Lip clearance too small. Too much feed.

(Table continued on p. 23-70)

Causes of Failures of Twist Drills—*Continued*

Indications	Causes
Drill will not enter work	Drill is dull. Lip clearance too small. Too heavy a web.
Hole rough	Point improperly ground or dull. No cutting compound at drill point. Feed too great. Fixture not rigid.
Hole oversize	Drill point improperly ground.
Chip shape changes while drilling	Drill becomes dull or cutting edges chipped.
Large chip coming out of one flute, small chip out of other flute.	Point improperly ground, one lip doing all the cutting.

THRUST, TORQUE, AND POWER FOR DRILLING. The design of drilling machines must be based on the forces involved when such machines are to be operated at ordinary ranges of feeds and speeds and in materials of low machinability.

Thrust and torque for various sizes of drills have been investigated at various times and by different investigators. (See Refs. 1, 2, and 3.) The results have varied somewhat because of differences in designs of drills used and variations in materials and testing equipment. It has been established, however, that torque and thrust for drilling can be expressed by the following equations:

$$\text{Torque } T = Cf^m d^n$$

where T = torque, foot-pounds; f = feed, inches per revolution; d = diameter of drill, inches; C = a constant depending on the material to be drilled, the design of drill, and the cutting fluid. The exponents m and n vary with the material to be drilled.

$$\text{Thrust } B = Kf^p d^r \text{ for aluminum and brass}$$

where B = thrust, pounds; and K = a constant corresponding to C in torque equation. The values of exponents p and r will vary with the material to be drilled.

$$\text{Thrust } B = Kf^p \left(\frac{d}{5} + \frac{w}{d}\right) \quad \text{for iron and steel}$$

where w = web thickness of drill, inches.

Tables of values for constants K and C as well as for exponents m, n, p, and r are to be found in the references cited.

As a practical reference, Table 5 gives values for thrust and horsepower as applied to drills operating at normal rates of feed.

Table 5. Thrust and Horsepower of Twist Drills at Indicated Rates of Feed
(National Twist Drill and Tool Co.)

Diameter of Drill	Feed per Revolution	Thrust, lb		Horsepower			
		Cast Iron	Steel	Cast Iron		Steel	
				100 rpm	100 sfpm	100 rpm	60 sfpm
1/8	.004		130			0.011	0.200
5/32	.0045		185			0.018	0.260
3/16	.005		245			0.028	0.340
1/4	.006		380			0.053	0.490
3/8	.008		550			0.210	1.308
1/2	.010	200	750	0.26	1.60	0.375	1.717
5/8	.011	275	1000	0.40	2.30	0.580	2.133
3/4	.012	325	1275	0.59	2.90	0.855	2.620
7/8	.013	400	1590	0.80	3.44	1.180	3.078
1	.014	500	1910	1.06	4.02	1.550	3.550
1 1/4	.016	700	2650	1.83	5.58	2.680	4.918
1 1/2	.016	850	3200	2.44	6.22	3.740	5.718

Thrust or feeding pressures should not be confused with horsepower required to drive a drill. It can be shown that only about 1% of the total power applied in drilling is used up to overcome the resistance due to thrust.

Both thrust and horsepower values in these tables are based on materials of average machinability. The tables for horsepower also make an allowance of 20% for friction losses in the machine.

All values are for sharp drills. Extra allowances for increases in thrust and horsepower due to dulling should be

Thrust 50 to 75%
Horsepower 40 to 60%

Horsepower requirements for a drill operating at any given speed in rpm may be found by multiplying the figures shown in columns under 100 rpm by the speed at which the drill is operating, and dividing by 100.

EXAMPLE. If a drill $1/2$ in. in diameter is operated at 500 rpm in steel, the power required would be $0.375 \times 500/100 = 1.875$ hp.

ABRASIVE PROCESSES

By R. E. W. Harrison *

25. ABRASIVE WHEELS †

Every grinding wheel has two components: *abrasive*, which does the actual cutting, and *bond*, which holds the abrasive grains while they cut. The retaining force with which the abrasive grains are held in place by the bonding material determines the *grade*, while the actual spacing of the abrasive grits themselves provides the definite characteristics known as *structure*.

ABRASIVES. There are two common types of manufactured abrasives used for grinding wheels and other abrasive products, *aluminum oxide* and *silicon carbide*. Both are products of the electric furnace and are marketed under various trade names, as Alundum, Aloxite, Borolon, Carborundum, Crystolon, et cetera. Emery and corundum, natural forms of aluminum oxide, contain impurities and are unsuitable for uniform quality production grinding wheels.

A typical aluminum oxide abrasive, Norton Alundum, is made by fusing bauxite in an electric furnace. Crystolon, a typical silicon carbide abrasive also a product of the Norton Company, is produced by electric furnace reaction of pure silica sand and coke. The aluminum oxide abrasives generally are used for grinding materials of high tensile strength, like carbon steel, alloy steel, high-speed steel, annealed malleable iron, tough bronzes, and other materials that are hard, tough, and strong. Silicon carbide abrasives are hard and sharp, but not as tough as the aluminum oxide abrasives. They are used for grinding materials of low tensile strength like gray iron, chilled iron, brass, soft bronze, aluminum, copper, stone, marble, rubber, cemented carbides, and other materials that are hard and brittle.

GRAIN SIZE. Numbers used to designate grain size represent the approximate number of openings per linear inch in the screen through which the grits will pass. Standard grain sizes from coarse to fine are 4, 6, 8, 10, 12, 14, 16, 20, 24, 30, 36, 46, 60, 70, 80, 90, 100, 120, 150, 180, 220, and 240. The fine flours are classified hydraulically to the sizes 280, 320, 400, 500, and 600.

BOND. There are six principal types of bonds used in grinding wheels.

1. **Vitrified bond** consists of a mixture of clays, subjected to a sufficiently high temperature to fuse to a molten, glass-like condition. The porosity and strength of this bond promote high stock removal, and its inelasticity helps in the attainment of high precision. It is not affected by water, acid, oils, or ordinary temperature variations.

2. **Silicate bond** consists basically of clays and silicate of soda, which at comparatively low temperatures form a hard cement. The silicate bond releases the abrasive grains more readily so that the wheels are milder acting and, therefore, are particularly suited for grinding edged tools and other work where heat generated in grinding must be kept at a minimum. Silicate bond is also used in making very large solid wheels.

3. **Shellac bond,** an organic bond consisting of shellac and other gums, has no porosity, high tensile strength, and good elasticity. Wheels are capable of producing highly refined finishes on camshafts and steel-mill rolls; are used also for grinding cutlery and for cut-off work requiring thin wheels.

---

* Revision of material originally prepared by R. T. Kent.

† Revised by E. T. Larson, Norton Co.

4. **Rubber bond,** consisting of rubber, either natural or synthetic, mixed with certain minerals in definite proportions, on vulcanization produces a desired hardness and toughness. Rubber-bonded wheels are used for most centerless control wheels and for precision ball race grinding; also for high-speed snagging where finish is important and for cut-off wheels where burr and burn must be held to a minimum.

5. **Resinoid bond** consists of synthetic resins. It is used for high-speed wheels in foundry cleaning rooms and billet shops, for sharpening and gumming saws, and for thin cut-off wheels. These wheels are designed to operate at 9500 sfpm; cut-off wheels at 16,000 sfpm.

6. **Magnesium oxychloride,** a cold set cement used as a bond in wheels and segments, chiefly for disk grinding.

GRADE is a term indicating the relative strength (holding power) of the bond which holds the abrasive grains in place. It does not express the hardness of the abrasive itself. A grinding wheel may be made of a very hard abrasive and still be a soft wheel with respect to cutting action. In general, with a given type of bond, it is the *amount* of bond which determines the hardness of grade. If the abrasive grains are easily broken out of the bond, the wheel is said to be soft. A wheel is of the proper grade when the cutting grains, as they become dulled, are released or fractured and either entirely new, sharp grains or new, sharp-cutting edges and points are presented to the work. Wheels that are too hard will glaze and must be resharpened by dressing.

While the ideal way to measure grade is to grind on each wheel, the best-known practicable method is to measure the resistance offered by the wheel to the penetration of a steel screw driver-like blade. Under a uniform pressure and twisting force, the blade will penetrate deeper into a softer wheel than into a hard one. Grades are designated by letters of the alphabet, so that there is a gradual change in hardness from an extremely soft wheel to an extremely hard one.

In the standard marking system adopted in 1944 by all the grinding-wheel manufacturers, the grade letters range from A to Z in the order of increasing "hardness." In other words, wheels in such grades as F, G, H, I near the beginning of the alphabet are relatively soft. Wheels around grade L, M, N are considered medium, and wheels in grades Q, R, S, etc., are hard. However, it should be borne in mind that this new marking system is a uniform system of marking only, and not of grinding action. In other words, wheels that happen to bear the same standard markings, if made by different wheel manufacturers, may not, and probably will not, produce exactly the same grinding action.

STRUCTURE is determined by the arrangement or spacing of the abrasive grits in the wheel. The same total volume of voids in two different wheels may be made up of a relatively small number of voids of large volume, or of a large number of voids each of small volume. The cutting action of two wheels of different structures will be different, although they may be of the same grain and grade.

Structure in a grinding wheel is denoted by a number. When the abrasive grains are close together relative to their grain size, the wheels have low structure numbers such as 0, 1, 2, 3. Wider spacing relative to the grain size is designated by higher structure numbers, such as 8, 9, 10, 11, 12. Some wheels, commonly referred to as being of the "open structure" or "porous type," have a special structural make-up that gives them a distinctive porous appearance. This type of wheel in soft grades has been found effective for broad-contact grinding, tool and cutter grinding, surface grinding, and internal grinding of large diameter holes.

WHEEL MARKING. Grinding wheels are marked with a combination of numbers and letters, called the *wheel marking*, which completely describes and identifies a wheel. In the new standard marking system adopted by all the grinding-wheel manufacturers a few years ago, there are six positions indicating a particular characteristic of the wheel:

Position No.	1	2	3	4	5	6
Designates	Abrasive	Grain size	Grade	Structure	Bond	Bond modification
Example	32A	46	J	5	V	BE

Position 1 denotes the type of abrasive material, A for aluminum oxide and C for silicon carbide. Numbers preceding the letter may be added by the manufacturer to indicate the brand of abrasive. The symbols in positions 2, 3, and 4 are explained in the preceding paragraphs under Grain Size, Grade, and Structure. Position 5 designates the bond material: V for vitrified, S for silicate, B for resinoid, R for rubber, E for shellac, and O for magnesite (oxychloride). Position 6 indicates any special manufacturing process and is a symbol chosen by the manufacturer. In the example, the complete marking is 32A46-J5VBE, which describes a wheel of Norton 32 brand Alundum abrasive, grain size 46, grade J, structure 5, vitrified bond of Norton BE type.

DIAMOND WHEELS. Wheels in which the abrasive surface consists of crushed and sized natural bort diamonds are used extensively for sharpening cemented carbide tools and cutters and for cutting carbide blanks. These wheels are made in a variety of sizes and shapes for use on carbide tool grinders, tool and cutter grinders, surface grinders, and other precision-type grinding machines. Diamond wheels are available in three different bond types, resinoid, metal, and vitrified. The resinoid-bonded are the fastest cutting, but the least wear resistant. The metal-bonded cut somewhat slower, but are the most durable. The vitrified-bonded approach the resinoid-bonded in rate of cut and the metal-bonded in resistance to wear. Each bond type has specific applications. The grit sizes most commonly used for carbide grinding are 100 for roughing, 220 and 320 for finishing, and 120 and 150 for both rough and finish grinding in a single wheel. Diamond wheels are available in several different grades of hardness, in three different diamond concentrations, namely, 25 (low), 50 (medium), 100 (high), and three common depths of diamond section, namely, $^1/_{16}$, $^1/_8$, and $^1/_4$ in.

Diamond wheels are operated at the same speeds as ordinary tool grinding wheels. For best results, they should be used wet, preferably with ordinary water-soluble grinding solution. If diamond wheels must be used dry, the depth of cut per pass should not exceed 0.0005 in.

26. FACTORS AFFECTING GRINDING-WHEEL SELECTION *

Selection of a grinding wheel for a given operation involves consideration or both the fixed conditions surrounding the job and the factors that may vary.

FIXED CONDITIONS. 1. **Material to Be Ground.** The physical properties of the material to be ground govern the type of abrasive to be used. Materials of high tensile strength, such as steel and the tougher varieties of bronze, as well as other materials that are hard, yet tough and strong, can best be ground with aluminum oxide abrasive wheels. The problem of different degrees of hardness, toughness, and sensitiveness to burning in metals is solved by using aluminum oxide abrasives of varying degrees of purity, strength, and fracture characteristics.

Materials of low tensile strength, which are penetrated easily, such as the soft bronzes, cast and chilled iron, aluminum, granite and marble, and glass, are ordinarily ground with silicon carbide abrasive wheels; also, the cemented carbides and other materials which are both exceptionally hard and brittle. The regular form of gray silicon carbide abrasive is used for general grinding, heavy-duty snagging, cylindrical, centerless, and internal grinding. The other form of silicon carbide abrasive has a characteristic light green color, and is generally preferred for grinding cemented carbide tools.

In general, hard dense materials require a relatively soft wheel. A large number of abrasive grains or cutting points in the wheel is necessary, since the penetration of each point is slight. Exceptionally hard materials, such as the cemented carbides, are best ground with open-structure wheels; likewise, soft, tough, and ductile materials.

2. **Amount of Material to Be Removed.** For relatively heavy stock removal, coarse-grain wheels with open structure should be used, particularly where maximum efficiency is desired and for rough work such as off-hand snagging of castings. Finish depends largely on grain size, except in precision grinding. Here, proper truing facilities and skillful grinding technique make possible an acceptable finish with relatively coarse-grain wheels.

It is a common mistake among production executives to think of grinding costs solely in terms of wheel cost. They overlook the more important factor of cutting speed. There are three factors to consider in computing grinding costs: (1) rate of stock removal; (2) wheel life; and (3) cost per unit of production. This includes direct labor cost, factory overhead, and wheel cost.

A very fast-cutting wheel may have a relatively short life and yet show a low *total cost* for the amount of material removed because both the direct labor and overhead costs are low for the amount of stock removed. Furthermore, the rate of production is high.

On the other hand, a hard slow-cutting wheel may last twice as long as a softer fast-cutting wheel. For the same amount of stock removal, the labor and overhead costs for such a wheel might be much higher, so that the total grinding costs would be much higher than in the preceding example. To be sure, if the wheel is too soft for fast cutting, the wheel has to be changed more frequently and work spoilage may result, so that some care must be used in selecting the right wheel for the job.

3. **Area of Contact.** The area of contact influences the selection of grain size, grade, and structure number. In general, fine grain is employed where the area of contact is small and a coarse grain where the area of contact is large. Cylindrical grinding is an example of relatively high unit pressure and small area of contact. Such conditions call for a wheel of medium to fine grain, medium structure, and medium grade.

---

* Revised by E. T. Larson, Norton Co.

Surface grinding, with the rim of a cup, cylinder, or segmental type wheel in contact with the work, is an example of high total pressure of wheel on the work, but low unit pressure. The wheel characteristics under such conditions would be a coarse grain, with wide grain spacing (open structure) to distribute the pressure per unit of area over a small number of cutting points, each subjected to sufficient pressure to cut effectively and also to provide ample chip clearance. The grade should be soft, in order that the dull grains may be released promptly, inasmuch as the forces tending to fracture them or tear them from the wheel are light.

4. **Type of Grinding Machine.** The grinding machine usually is already installed and imposes conditions that must be considered in wheel selection. Machines that are light and flimsy, or of the flexible type, require harder wheels than heavy, rigid machines. The combination of speeds and feeds on some precision machines may affect the grade of wheel desirable for best results. Surface-grinding machines employing cup wheels require softer wheels of more open structure than similar machines using straight wheels.

VARIABLE FACTORS. Wheel Speed. Too slow a speed consumes abrasive without corresponding useful work. Excessive speed may result in hard grinding action and danger of breakage. It is best to operate a grinding wheel at or as near as possible to the speed recommended by the maker. The grit sizes, grades, and bond types recommended for given grinding operations are based on the assumption that the wheels will be operated at the recommended speeds. If these speeds cannot be used, compensation should be made in the grade selection. Table 1 gives the peripheral speeds recommended for various classes of work.

Table 1. Recommended Wheel Speeds for Various Classes of Grinding

Type of Grinding	Wheel Speed, surface feet per minute
Cylindrical grinding (vitrified)	5500–6500
Cylindrical grinding (resinoid)	6500–9500 *
Surface grinding	4000–6000
Internal grinding	2000–6000
Internal grinding (diamond wheels)	5000–6500
Cutter and tool grinding	4500–6000
Cutting-off (rubber, shellac and resinoid)	9000–16000 *
Snagging, off-hand grinding (vitrified wheels)	5000–6500
Snagging (rubber and resinoid wheels)	7000–9500

* Higher speed recommended only if bearings, protection devices, and machine rigidity are adequate.

Work Speed. In machine grinding, high work speed tends to wear the wheel faster than slow work speed. Wheel wear depends on the ratio of wheel speed to work speed, both in surface feet per minute. The higher the ratio, the less work the wheel is required to do in a given time, and the wheel wears at a lower rate. A decreased ratio, resulting from increased work speed, requires the wheel to do more work in a given time and to wear faster.

In general, the longer the arc or the larger the area of contact in precision grinding operations, the faster should be the work speed, in order to have the wheel cut properly. In off-hand grinding the pressure employed in forcing the work against the wheel, or the method of applying the work, influences the grade selection. The more severe the pressure and application conditions, the harder should be the wheel in order to give economical wheel life. This relationship also exists in semi-automatic and high-production precision grinding, such as crankshaft and camshaft grinding. Work speed will also vary somewhat according to the material being ground, approximately as shown in Table 2.

Table 2. Work Speeds in Grinding

Material	Speed at Time of Cutting,* surface feet per minute
Soft steel	30–50
Hard steel	70–100
Cast iron	200–400
Aluminum	100–200

* Lower side of range used for roughing cuts and higher for finishing.

Skill of Workmen. Grinding costs on off-hand grinding may vary as much as 100% on some work with the same kind of machine in the same shop, because of the difference in the method of applying the work to the wheel, and the variation in the skill and knowledge of the different workmen. Even in machine grinding, the operator can vary the results by his method of handling the machine.

The foregoing considerations are summarized in Table 3. Table 4 gives the complete marking of wheels recommended for the most common materials that may have to be ground. The recommendations presuppose that operating conditions comply with good grinding practice.

Table 3. Factors Influencing the Selection of Abrasive Wheels

Selection of	Influential Factors	Kind of Wheel	Material Ground, Result Desired, or Condition to Be Met
Abrasive	Physical properties of material ground	Aluminum oxide	Carbon, alloy, or high-speed steel; annealed malleable iron; wrought iron; tough bronzes; tungsten, etc.
		Silicon carbide	Gray iron; chilled iron; brass; soft bronze; aluminum; copper; marble; granite; pearl; rubber; leather; very hard alloys as tungsten carbide, etc.
Grain Size	Amount of material to be removed	Coarse grain	Fast removal of stock
	Finish desired	Fine grain	Fine finish
	Physical properties of material to be ground	Coarse grain	Soft, ductile materials
		Fine grain	Dense, hard, or brittle material
Grade	Physical properties of material to be ground	Hard wheel	Soft material
		Soft wheel	Hard material
	Area of contact	....	Hardness increases as area of contact decreases
	Wheel speed	Hard wheel	Low wheel speed
		Soft wheel	High wheel speed
	Work speed	Hard wheel	High work speed
		Soft wheel	Low work speed
	Condition of grinding machine	Hard wheel	Machine in poor condition
		Soft wheel	Machine in good condition
	Skill of operator	Harder wheels	Unskilled operator; piece work
		Softer wheels	Skilled operator; day work; economical production
Structure	Physical properties of material to be ground	Wide spacing	Soft, tough, ductile materials
		Close spacing	Hard, brittle materials (except cemented carbides)
	Finish desired	Wide spacing	Medium or coarse finish
		Close spacing	Fine finish
	Nature of operation	Wide spacing	Snagging; operations with flexible application of pressure; surfacing
		Medium spacing	Cylindrical, centerless, tool and cutter grinding
		Close spacing	Heavy pressures tending to deform wheel face
Bond	Wheel dimensions	Vitrified	For general use; rapid removal of stock
		Silicate	Solid wheels of very large diameter
		Resinoid Shellac Rubber	Thin cutting-off wheels; wheels subject to deflection
	Operating speed	Vitrified	Wheel speeds up to 6500 surface ft per min
		Resinoid Shellac Rubber	Wheel speeds above 6500 surface ft per min
	Finish desired	Resinoid Shellac Rubber	High finish where stock removal is not a factor
		Silicate	To replace sandstone on cutlery, etc.

Table 4. Grinding Wheel Recommendations

27. WHEEL TYPES, SPEEDS

WHEEL SHAPES. While a tremendous variety of wheel shapes are in use and can be had, industry has standardized on wheel shapes which can be obtained from stock. Nonstandard wheels, however, can be obtained on order. The standard shapes of wheels and wheel faces are shown in Figs. 1 and 2. Wherever possible, the design of parts which are to be ground should contemplate use of the simplest possible standard wheel shape for maximum economy.

OPERATING SPEED. Not all types of wheels possess equal strength; consequently it is not safe to operate them all at equal speeds. As a general rule, vitrified and silicate-bonded wheels are classified in one group and the organic-bonded (shellac, rubber, and resinoid) in another. For vitrified and silicate wheels, which have relatively low elastic modulus, a maximum operating speed of 6500 sfpm has been established. Wheels in the softer grades and of relatively coarse grain size should not be operated as fast as this. The organic-bonded wheels are stronger and can be operated at higher speeds with safety. A maximum operating speed of 9500 sfpm has been established for this group, with the exception of thin cut-off wheels, which may be operated up to 16,000 sfpm under certain conditions. In the organic-bonded group, as in the vitrified and silicate, the operating speeds for the softer and coarser wheels should be lower.

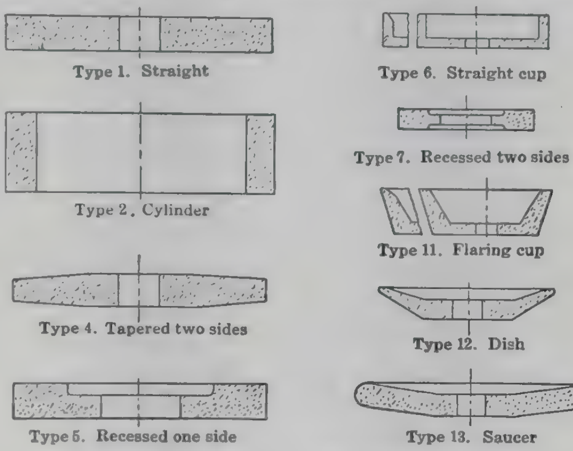

Fig. 1. Standard grinding wheel shapes.

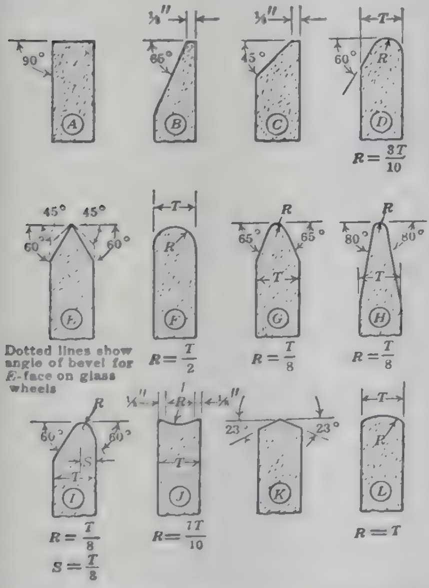
It is general practice for the wheel manufacturer to show the maximum operating speed on the blotters, or tag, accompanying the wheel. It is also standard practice to test all wheels 6 in. in diameter, and larger, at speeds sufficiently higher to insure a reasonable factor of safety. Table 5 shows maximum peripheral speed per minute permitted by the ASA Safety Code for various types of wheels and bonds.



Dotted lines show angle of bevel for E-face on glass wheels

Fig. 2. Standard shapes of grinding wheel faces.

INTERNAL GRINDING OF SMALL AND MEDIUM-SIZE HOLES. C. R. Alden (Ref. 1) describes the grinding of holes as small as $^1/_{16}$ in. in diameter. An air turbine was used to give a spindle speed of 65,000 rpm. The wheel was a mounted point, that is, an abrasive tip cemented on a steel shank, substantially less in diameter than the tip, which, in turn, was smaller than the hole to be ground. An important consideration in the internal grinding of small holes is the type of grinding spindle and the bearings used. A solid projection-type of spindle, in which the wheel is mounted on an integral projection of the spindle, was found to be best. The projection should be of the largest possible diameter and shortest possible length consistent with the diameter of the hole to be ground. This will limit the amount of wheel wear that can be permitted, since allowance of excessive wheel wear will necessitate a spindle and bearings that will lack rigidity. It is recommended that wheels used for grinding 2-in. holes be allowed $^1/_2$ in. reduction of diameter by wheel wear, and that they then be transferred to the grinding of 1 $^1/_2$ in. holes, with a further allowance of $^3/_8$ in. for wheel wear, after which they could be used for the grinding of 1 $^1/_8$ in. or 1-in. holes. The wheel thus can be used up, and at the same time the conditions under which it works will be those of maximum efficiency. Figure 3 shows the spindle speeds recommended for the grinding of small holes. It should be noted that high-frequency motor-driven spindles have been developed and are expected to prove satisfactory along with the air turbine type of spindle for the speeds in excess of those conveniently obtainable through belt drives.

Table 5. Maximum Permissible Speeds for Grinding Wheels

Classification Number	Types of Wheels (See also Fig. 1)	Vitrified and Silicate Bonds			Organic Bonds

satisfactory along with the air turbine type of spindle for the speeds in excess of those conveniently obtainable through belt drives.

GRAIN DEPTH OF CUT. An analysis of the action of the wheel when in operation shows how theoretical considerations bear out the truth of the empirical rules for the use of grinding wheels in machine grinding. A paper by George I. Alden (Ref. 2) gives the essential distinction between the radial or real depth at which the wheel cuts and the depth which the abrasive grain in the wheel cuts into the material being ground. The latter depth is called the *grain depth of cut*. This grain depth of cut is the controlling factor in securing the correct working of the wheel. A formula is deduced for computing the grain depth of cut, the application of the analysis is explained, and these conclusions reached by Professor Alden: (1) Other factors remaining constant, increase of work speed increases grain depth of cut, and makes a wheel appear softer. (2) A decrease of wheel speed increases grain depth of cut. (3) Diminishing the diameter of the wheel increases the grain depth of cut; increasing the diameter of the wheel decreases the grain depth of cut. (4) Decreasing the diameter of work increases the grain depth of cut; conversely, increasing the diameter of work decreases the grain depth of cut. A table of arcs of contact of wheel and work for a limited range of diameters is given, also a table of values of one of the factors in the formula for grain depth of cut.

W. H. Chapman (Ref. 3), basing his study on Alden's paper set forth above, gives a mathematical analysis of the laws involved in cylindrical grinding and an analysis for grinding action for both draw-in and traverse cuts, deriving formulas and from them drawing practical conclusions as to the best methods to follow for maximum grinding efficiency.

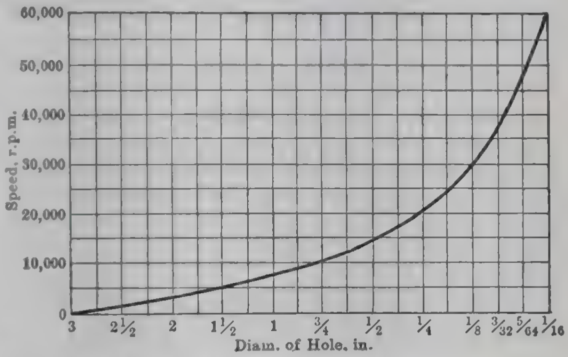

FIG. 3. Wheel speeds for grinding small holes.

Draw-in Cuts. For draw-in cuts, the maximum depth of chip, in inches, corresponding to Alden's grain depth of cut, is given by

$$G = \frac{\mu u}{V}\sqrt{\frac{2f}{r}} \text{ approximately} \qquad (1)$$

where G = maximum depth of chip, inches; μ = intervals between grains of wheel in fractions of an inch; u = work speed, feet per minute; V = surface speed of wheel, feet per minute; f = depth of cut, inches, on work radius; r = radius of work, inches.

The index of the wheel-wearing action, W_1, due to grinding, is

$$W_1 = \frac{\mu u}{V^2}\sqrt{\frac{2f}{r}} \qquad (2)$$

The actual wheel-wear can be computed by multiplying the value of W_1 by a constant derived by experiment, which may be taken as (1800×10^4). The amount of metal removed per minute may be determined by

$$P = 2\pi r f w \times \text{rpm} \qquad (3)$$

where P = cubic inches of metal removed per minute; w = width of wheel, inches, and rpm = speed of rotation of the work, other notation as before.

Table 6 compares wheel wear and quantity of metal removed at different work speeds in a given machine, as calculated from the above formulas. Note that wheel-wear values increase rapidly as work speed increases. The value of 0.0166 for work 1 in. diameter at 53 rpm becomes 0.1040 for work 4 in. diameter at 167 rpm. A wheel sufficiently soft to cut freely in the first case would wear so fast as to be nearly useless in the second case.

Table 6. Comparison between Wheel Wear and Quantity of Metal Removed at Different Work Speeds

(Wheel diameter, 18 in.; surface speed, 6000 ft per min; diametral feed per work revolution (automatic feed), 0.001 in.; grain of wheel, 46 Alundum; material ground, mild machinery steel.)

Work Speed, rpm		Work Diameters			
		1 in.	2 in.	3 in.	4 in.
53	Production *	.0835	.1670	.2500	0.3340
	Wheel wear	.0166	.0236	.0290	0.0334
72.5	Production *	.1140	.2280	.3420	0.4560
	Wheel wear	.0226	.0319	.0390	0.0450
87	Production *	.1370	.2740	.4110	0.5480
	Wheel wear	.0273	.0387	.0475	0.0546
101	Production *	.1586	.3172	.4758	0.6344
	Wheel wear	.0316	.0448	.0540	0.0635
138	Production *	.2160	.4320	.6480	0.8640
	Wheel wear	.0433	.0612	.0645	0.0865
167	Production *	.2620	.5240	.7860	1.0480
	Wheel wear	.0522	.0740	.0910	0.1040

* In cubic inches of metal removed per minute.

Where the wheel-wear values are nearly the same, however, the same wheel will act properly in both cases, as, for instance, on 1-in. work at 138 rpm and 4-in. work at 72.5 rpm. From Table 6, and by experimental tests with various wheels, certain ranges of wheel-wear values may be found to correspond to different grades of suitable grain size and abrasive for the material to be ground, and wheel-wear indices may be computed for any set of conditions to enable the proper wheel to be selected.

Production can be increased with a minimum increase in wheel wear by an increase in the feed, up to the limit of the grain penetration. An example in the paper shows that doubling the feed approximately doubled the production but increased the wheel wear only 35%. Doubling the work speed, on the contrary, doubled both production and wheel wear.

Traverse Cuts. The index of wheel wear for traverse cuts is

$$W_t = \frac{\mu u}{V^2} \frac{u}{\sqrt{T^2 + u^2}} \sqrt{\frac{2f}{r}} \tag{4}$$

where T = traverse speed, feet per minute, other notation being as before. The expression $(u/(\sqrt{T^2 + u^2}))$ is known as the traverse factor. Where T is large with respect to u the factor is appreciably less than unity, but as the speed u increases the reduction in wheel wearing action is less pronounced. A table of wheel-wear values for traverse cuts can be made by multiplying the traverse factors determined as above by the wheel-wear value for the corresponding work speed and work diameter for draw-in cuts, such as are given in Table 6. Table 7 is such a table compiled for the same machine as Table 6. By assigning certain wheels to specified ranges of wheel-wearing action, the proper wheel for traverse cuts may be selected from Table 7. The wheel used, however, would be somewhat softer in the traverse cut for the same index figure, because the actual depth of cut does not follow the indicated depth, as shown by the feeding mechanism, as closely for traverse work as for draw-in work. The following wheels are found to be satisfactory for traverse cuts on mild steel under the assumed conditions:

Table 7. Wheel-wear Values for Traversed Cuts

(For same conditions as given for Table 6)

Traverse, ft per min	Work, rpm	Lead, in.	Work Diameters			
			1 in.	2 in.	3 in.	4 in.

Practical Conclusions. These practical conclusions are drawn from the foregoing mathematical analysis: The power drive must maintain the speed constant except as changed by the operator. The wheel must be in good running balance and in absolute truth, and held in position relative to the work within the closest possible limits. The work must be accurately held with respect to the wheel and must be uniformly rotated. The relative traverse between work and wheel must be uniform. The work must be rigidly supported over its entire length and no vibration allowed to occur between centers. Feeding must be at such a rate that the feed increment never exceeds the maximum grain penetration. Work must be kept at a uniform temperature and local heating prevented. A copious supply of grinding compound should be directed to the arc of contact at all times. In truing a wheel with a diamond, the cooling medium is vital to accuracy. Never feed a diamond over 0.001 in. per traverse. Do not try to use a single wheel for a variety of work sizes or materials.

FACTOR OF SAFETY. Since the centrifugal force tending to break a wheel increases as the square of the speed, it is, at 9000 sfpm 2.3 times greater than at 6000 sfpm, and 3.3 times greater than at 5000 sfpm. These values, 2.3 and 3.3, are called the established factor of safety for the operating speeds mentioned.

$$\text{Established factor of safety} = \text{testing speed}^2 \div \text{operating speed}^2$$

$$\text{True factor of safety} = \text{breaking speed}^2 \div \text{operating speed}^2$$

The true factor of safety cannot be calculated unless the breaking speed actually is measured. Experience shows the true factor of safety to be, usually, many times greater than the established factor.

The forces tending to break grinding wheels are due to other causes besides speed of rotation. Among them are poor mountings, wheel flanges of unequal diameter, unrelieved flanges, expansion from excessive and rapid heating of one peripherv, work catching between wheel and work rest, improper grinding on side of wheel, and excessive out-of-truth or out-of-balance conditions. These conditions are cumulative and increase the breaking stresses due to rotation. Since these conditions exist, the established factor of safety is kept large. If the grinding conditions are correct, the wheel which has been subjected to the speed test should not give trouble, as it has been established that it is sufficiently strong to withstand the stress due to ordinary grinding conditions. A thorough investigation of a grinding wheel broken in operation usually will show the breakage to have been due to faulty operating conditions and not to the wheel itself.

28. GRINDING MACHINES

Grinding machines may be classified as cylindrical, internal, centerless, surface, and special grinders, based on the general character of the work. Each of these classes may be further subdivided according to special characteristics either of work or machine. The following paragraphs cover the types of grinding machines most commonly used, together with their fields and limitations.

CYLINDRICAL GRINDING MACHINES. Plain Grinders. Cylindrical grinding machines for general-purpose plain grinding of cylindrical surfaces such as spindles and axles, range from 3 to 36 in. swing. Standard sizes are 3 by 12 in.; 4 by 18 in.; 6 by 18 in.; 6 by 30 in.; 10 by 18 in.; 10 by 36 in.; 10 by 48 in.; 10 by 72 in.; 10 by 96 in.; 10 by 120 in.; 14 by 36 in.; 14 by 48 in.; 14 by 72 in.; 14 by 96 in.; 14 by 120 in.; 14 by 144 in.; 14 by 168 in.; 16 by 36 in.; 16 by 48 in.; 16 by 72 in.; 16 by 96 in.; 16 by 120 in.; 16 by 144 in.; and 16 by 168 in. Machines 20 in. and larger generally start at 96 in. and run up to 192 in. in 2-ft increments.

Machines are built with hydraulic, mechanical, or hand traverse, or with all three, of both table and grinding wheel head. Grinding wheel and work drives usually are from separate motors through V belts. Work tables of the machines have power headstocks and sliding tailstocks. Mounted on the longitudinally traveling main table of the machine, the work table can be swiveled up to about ten degrees relative to the main table travel, adjustment varying with different size machines.

Cylindrical grinders can be built to function automatically or semi-automatically, through a complete cycle, producing work ground within predetermined limits. They also may be fitted with attachments for cam, roll, or crankshaft grinding, although for regular production of this character special machines are advisable. For grinding faces of shoulders and the adjacent cylindrical surfaces, cylindrical grinders may be built with the wheel slide set at an angle of 45 degrees to the axis of the work, a V-shaped wheel being used. (See Fig. 4.)

Universal Grinders. Second most widely used grinding machine for general-purpose work, the universal machine, was originally a tool-room grinder but is now a useful production unit. In addition to features offered by plain grinders, universal machines are provided with a swiveling headstock and a swiveling wheel head. Completely flexible, these machines are well suited for production of small- or large-quantity lots of parts requiring face as well as cylindrical and taper grinding. Standard machines range in size from 12 to 18 in. swing and from 24 to 72 in. between centers.

INTERNAL GRINDERS comprise a reciprocating wheel head carrying a grinding wheel on a spindle long enough to reach to the bottom of the hole, and a work head in which the work can be rotated while in contact with the wheel, both carried on a suitable bed or frame, with provision for adjustment of both wheel and work. The field of the internal grinder is the finishing of holes in gears, bushings, bearings, etc., and the finishing of the inside surface of cylinders, as automotive cylinders. The cylinder grinder is a special form of internal grinder, and in one type the wheel head gives a planetary motion to the wheel spindle. H. L. Blood (Ref. 4) describes an automatic internal grinder which rough-grinds, trues the wheel, finish-grinds the hole to size, runs the wheel out of the hole, and brings all parts to the rest position. The range of capacity of internal grinders is holes from 0.040-in. to 50-in. in diameter up to 16 in. deep.

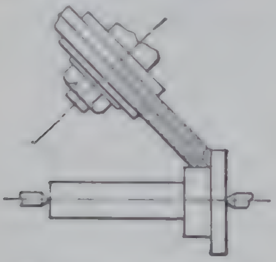

FIG. 4. Arrangement for grinding shoulders.

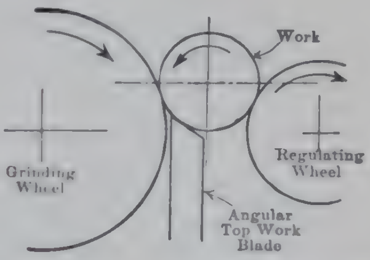

FIG. 5. Principle of centerless grinding.

CENTERLESS GRINDERS are a special form of cylindrical grinder. Instead of the work being supported on centers, it is supported on a work rest and held against a regulating wheel. (See Fig. 5.) By setting the regulating wheel at an angle to the grinding wheel, the former will act as a feeding device and will traverse the work past the grinding wheel. The regulating wheel is positively driven, and its speed determines the rotational speed of the work. The centerless grinder operates on a diametral dimension instead of on a radial dimension of the work, as in grinders where the work is held on centers, and therefore under certain conditions it will remove double the amount of metal in a given time. On slender work, much higher grinding pressure can be used in the centerless machine, as the work is rigidly supported by the work rest and regulating wheel, whereas when supported on centers it tends to spring away from the wheel under heavy pressure.

External centerless grinders can be either of the through-feed or in-feed type. With through-feed, machines available handle parts from about 0.020 in. to about 7 in. in diameter and lengths up to 20 ft or more. Internal centerless machines handle parts with bores from 1/4 to 24 in. Belt centerless external grinders handle diameters up to 9 in. by practically any length. Centerless thread grinding machines grind from the solid threaded parts or shafts with 8- to 80- pitch threads, 1/8 to 36 in. in length and up to 5 in. in diameter.

SURFACE GRINDING MACHINES. Surface grinders are divided into several distinct classes, such as (1) horizontal spindle, reciprocating table, using periphery of wheels; (2) horizontal spindle face grinder with reciprocating table, using segments; (3) horizontal spindle, rotary table; (4) vertical spindle, rotary table; and (5) vertical spindle, reciprocating table. Surface grinding machines vary all the way from small tool-room machines, using 7 by 1/2 in. wheels, to massive face grinding machines, using 48 and even 60 in. diameter segmental wheel chucks.

Reciprocating tables usually are traversed hydraulically. In certain machines the rotating table can be set at an angle to permit grinding of concave or convex surfaces. Both direct motor drive and belt drive of grinding wheels are available. The capacity of the standard reciprocating table grinders ranges from work 6 by 18 in. to 30 by 192 in. Rotating-table surface grinders are built with tables up to 60 in. in diameter. Work usually is held on the table by magnetic chucks.

Disk grinders are a form of surface grinder using abrasive disks mounted on a steel backing. The work is ground against the side of the disk. Single-spindle machines, with a disk on each end of the spindle, are built to use disks up to 40 in. in diameter. The work is supported on tables, equipped with either hand or power feed. The spindles are driven either direct from the motor or through V belts.

The double-spindle disk grinder is a machine for grinding two parallel surfaces. It comprises, virtually, two single-end disk grinders, mounted on a common base, the wheel spindles being in line, with the wheels facing each other. The work, supported by a table, is fed in between the wheels, which are spaced the correct distance apart. Wheel spindles are driven direct from the motor or through V belts. These machines are built in various sizes, with disks ranging from 15 to 72 in. in diameter and with maximum opening between wheels ranging from 20 to 30 in.

Face grinders are a form of surface grinder in which the work travels past the side of a wheel, carried on a horizontal spindle mounted at right angles to the line of travel of the work. The wheel grinds the vertical surface of the work at right angles to the surface of the table. The table is traversed hydraulically, and the wheel is driven by silent chain or V belt. Work can be held by bolting to the table or to angle plates or by magnetic chucks. These machines are used for surface grinding and for the grinding of machine knives, shear blades, etc. Tables range from 22 to 27 in. wide and from 60 to 168 in. long.

SPECIAL GRINDING MACHINES. Tool and cutter grinders are designed primarily for grinding of reamers, milling cutters, etc. In their simplest form they comprise a motor-driven grinding wheel and a pair of centers upon which the work is mounted, carried on a table that can be traversed past the wheel by hand. More elaborate machines comprise a power-operated swiveling table, a power-driven headstock to permit the machine to be used for cylindrical grinding, and attachments that permit of internal grinding and various forms of surface grinding. The capacity of tool grinders ranges usually up to 12 in. diameter swing by 20 to 27 in. between centers.

Roll Grinders. Roll grinding machines are cylindrical grinders of 20, 24, 28, 32, and 36 in. swings by 96, 120, 144, 168, or 192 in. lengths between centers. These are standard sizes. Special machines have been built up to 60 in. swing by 26 ft long between centers. Roll grinding machines are built with the work traversing past a grinding wheel in a fixed position or with the wheel traversing past the work. Rolls are crowned or concaved by moving the wheel, by appropriate mechanism, away from, or toward, the wheel as the wheel traverses it.

Cam and shape grinders are a special form of cylindrical grinder. In these machines, the work is rotated in a swinging member and is moved toward and away from the grinding wheel by means of a master cam in contact with a roller. The master cam is on the swinging member, the roller being fixed on the machine. Where the cams are integral with the camshaft, they are carried on centers in the machine, one pair being in the master cam spindle and the other in a footstock mounted on the swinging member. Single cams are mounted in fixtures or on arbors carried by the master cam spindle. For high production, as automotive camshafts, completely automatic machines are used. One type is a hydraulically operated machine that successively grinds each cam to size, indexing after each grinding operation. When the last cam is ground, the table reverses, returns to the starting position, and the work stops rotating. The wheel is trued automatically by a diamond, and its position changed to compensate for the truing. The table then stops in the loading position. This machine, made by the Norton Co., has a swing over the rocking bar of 5 in. Length of work between centers is 30, 36, or 42 in.

29. STOCK ALLOWANCE AND GRINDING TOLERANCES

ALLOWANCE FOR GRINDING. The amount of stock to be left for grinding varies with character of the work and type of machine. In cylindrical grinding the practical minimum is about 0.005 in., but because of variables such as warpage it may run up to 0.025 or 0.030 in. For economy the stock allowance should never exceed 1/16 in. In internal grinding the stock might vary from as little as 0.004 in. for holes around 1/8 in. diameter up to 0.035 in. for holes around 8 in. diameter. On centerless work, normal allowance for rough grinding may run to 0.010 in. and for finish grinding 0.001 to 0.002 in. above the high limit.

HORSEPOWER REQUIRED FOR GRINDING varies directly with the quantity of metal removed. R. E. W. Harrison gives (Ref. 5) the relation between horsepower and metal removal in centerless or controlled cylindrical grinders as follows:

Horsepower at grinding wheel spindle	5	10	15	20	25	30	35	40
Metal removal capacity, cubic inches per minute	1/2	1	1 1/2	2	2 1/2	3	3 1/2	4

GRINDING TOLERANCES have decreased with improvements in grinding machines, grinding wheels, and gaging devices. On cylindrical grinding, tolerances in diameter of ±0.00001 in. are possible of attainment when an automatic sizing device similar to a Nortonizer (Norton Co.) is used, if the machine and temperature conditions approach ideal. In out-of-roundness and taper, tolerances as small as 0.00005 in. are practicable. Readily held tolerances, however, range around ±0.0001 to 0.0005 in., with surface finish as fine as 4 to 5 microinches rms.

30. HONING, LAPPING, AND SUPERFINISHING

HONING is a term applied to the refined grinding of cylindrical surfaces. It is used for the accurate finishing of automotive cylinders, compressor cylinders, cylinders in hydraulic and refrigeration units, bushings, bearings, rods, etc. It consists essentially in the passage of a honing stone or stones in an axial direction through the bore, the hone being rotated at the same time. J. W. Hindes and J. G. Young (Ref. 6) state that a ratio of about 1 to 3 of reciprocation to rotation speed gives the most satisfactory results (65 to 70 surface ft per min reciprocation, 200 ft per min rotation). If the hone is hard and tends to glaze, this condition can be corrected by increasing the ratio of reciprocating to rotating speed.

The hone usually is a form of expanding segmental wheel, whose surface is formed by a series of abrasive stones carried in a holder. Means are provided to expand the stones to the wall of the cylinder being ground, and to hold them against it under pressure, while the hone is reciprocated and rotated. Wear of the stones is compensated by floating cones in the holders which feed the stones outward and maintain them in parallelism.

J. A. Carlin (Ref. 7) describes a method of honing blind end bores, by shifting the center of pressure on the abrasive stones toward the blind end to compensate for the loss of abrasive effect resulting from inability of the hone to overrun the end of the cylinder. J. E. Kline (Ref. 8) illustrates a fixture used for precision finishing by honing connecting rod crankpin bores.

Honing is primarily a surface-refining method intended to correct internal or external cylindrical geometry of parts. Although as much as 0.090 in. can be removed from a bore in honing, stock removal should be as small as possible for best economy. Honing will remove out-of-roundness, high spots, and taper, but will not correct position or alignment of a hole, bore, or diameter. Honing generates surface finish entirely independent of stock removal.

Accuracy in modern honing operations can be held within 0.0005 to 0.001 in. total variation for roundness and straightness with diameters over 4 in.; 0.0003 to 0.0005 in. on diameters from 1 to 4 in.; and on bores below 1 in. tolerances are usually within 0.0001 to 0.0003 in. In general, tolerances of ±0.0001 to 0.00025 in. are common, and particularly fussy jobs have been held to a total variation of 0.000025 in. but at a cost in slower production. Straight-line honed rods can be finished within 0.0001 to 0.0002 in. on roundness and taper.

Surface finish in hard steel may run as low as 1 microinch, rms; in cast iron, soft steel or bronze may run to as low as 3 microinches; and with aluminum a finish quality as fine as 15 microinches can be produced. Finest finish can be attained economically, as a rule, only when metal removal is small.

Honing, in general, should not be considered for diameters under $^1/_4$ in. Vertical honers will handle work up to 30 in. in diameter and 6 to 7 ft long. Horizontal machines will handle bores in diameters up to 50 in. and lengths to 70 ft. External work can be honed in diameters up to 6 in. and lengths from 2 to 12 ft.

Lubricant. Kerosene or mineral seal oil is generally used as a coolant and lubricant in honing cast iron and other metals. Turpentine gives a freer cutting action on bronze and brass. Water is unsatisfactory.

LAPPING produces exceedingly smooth and highly accurate surfaces, either flat, cylindrical, tapered, shouldered, or contoured. A lap, usually of cast iron, charged with fine abrasive, is rubbed against the surface of the work either by hand or by machine. Since about 1930, a lap consisting of fine abrasives bonded together has been used in many instances to replace the metal lap charged with loose abrasive. Abrasive-coated paper laps also are used. Laps are used with kerosene and lard oil lubricants.

Formerly limited in use to the production of precision surfaces in gages and measuring instruments, lapping has since 1930 been generally adopted as a production process in many industries, particularly the automotive. In this industry, it is used for the finishing of crankpins, bearings, piston rings, ball-bearing races, valve tappets, and other wearing parts. Lapping tolerances of 0.00005 in. in diameter and 0.000025 in. in straightness and roundness are possible of attainment.

Sydney Player describes (Ref. 9) the lapping of plug gages 0.875 in. in diameter ±0.00002 in. Two lapping operations were required. The grinding limit was +0.00015 to +0.0003 in. Rough lapping with M-304 American Optical emery brought the gages to within 0.00005 in. of finished size. For finish lapping, the laps were hand scraped and worked together with levigated alumina until the surfaces of the laps were mirror finished. The author also describes lapping, in lapping machines, of piston pins to limits of 0.0001 in. for straightness and roundness, the production being 500 pins per hour.

Stock allowance in lapping should never exceed 0.0005 in., preferably not over 0.0002 in. for rough lapping or 0.0001 in. for finish lapping from a rough lapped surface. Preliminary operations should be grinding or honing and should be as accurate as possible relative to geometrical and location accuracy because lapping provides little correction for these factors.

Honing machines using charged laps can be used to lap parts that fall within the size ranges mentioned under honing. Hand-operated centerless lappers using a charged lapping roll and a control roll, both of which are driven, can be employed to lap parts from 0.030 to 10 in. in diameter.

Vertical-spindle lapping machines consist essentially of a pair of laps which may be rotated independently of each other and in opposite directions if desired. The work to be lapped, which may be either cylindrical or flat, is carried in work holders, which position the work between the two laps and at the same time move it between the lap faces with a planetary motion in a constantly varying line of travel relative to the lap surfaces. For cylindrical work, the pieces are carried in the work holder at an angle to radial lines. An eccentric motion imparted to the work holder, in conjunction with the nonradial position of the work, causes all portions of the surface to come in contact with the laps and a true lapped surface is produced. The capacity of lapping machines ranges up to 3 in. in thickness or diameter by 6 in. long.

The centerless lap-grinding or lapping machine is similar in its principle of operation and in general construction to the centerless grinding machine. The lapping is done by wheels of finely divided abrasive suitably bonded. The lapping wheel is driven at a speed of 150, 195, or 225 rpm. Through-feed work from $^1/_2$ to 3 in. in diameter and of any length can be lapped in the centerless machine. By means of special equipment, work which cannot be passed transversely through the machine can be lapped in diameters of $^1/_4$ to 6 in. and 15 in. long.

SUPERFINISHING* complements the dimension-creating efficiency of the grinding operation by removing defective surface conditions. Ground surfaces have two general types of defects, geometrical and metallurgical. In addition to the visible spiral ridge, there may be chatter and feed marks. In plunge grinding, parallel ridges are characteristic. The heights of all these defects are tremendous as compared to the size of an oil molecule. They readily penetrate an oil film to result in true metallic contact and rapid wear.

When a hardened surface is ground, the objective is always defeated to some extent because the heat of grinding alters the applied heat treatment. A large amount of investigation of this condition by the writer has shown that the "burning" of the average hardened and ground surface extends slightly deeper than the last vestiges of the grinding scratch.

Another result of the inefficient removal of stock by the negative angles of the abrasive grit is the distortion of the crystalline structure to an appreciable depth. Furthermore, there is a production of partially loosened splinters of metal covering the surface which usually may be observed in the oil oozing from a newly started bearing.

In Superfinishing, the spurious layer of metal resulting from the foregoing conditions is removed by the mild scrubbing action of a bonded abrasive applied to the rotating surface under low pressure and a flood of light mineral oil lubricant (Fig. 6). An appropriate motion is always imparted to the abrasive or "stone" to prevent repetition of the grit paths and to cause each of them to pass over several of the various heights of the grinding defects. More efficient cutting is thus secured together with a much greater tendency to generate a true geometry of surface.

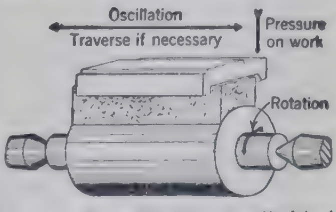

FIG. 6. Superfinishing a cylindrical surface. (Courtesy of Gisholt Machine Co.)

Surface shapes that can be superfinished are somewhat limited by their degrees of symmetry. Cylinders, cones, flat circles, and spherical sections are examples of the most easily performed operations. There are numerous borderline applications; for example, most reamers are readily Superfinished because their lands are contained in one cylindrical plane (Fig. 6); and flat surfaces can deviate somewhat from a true circle, but a square is usually difficult because the stone will not be equally supported by the corners and the narrow dimension during rotation of the part. Flanges or shoulders seldom interfere with work on a cylinder, but the flange surface itself may offer a problem. Any diameter or length of cylinder can be done except that adequate technique and equipment have not yet been developed for diameters as small as perhaps $^3/_{32}$ in. Likewise, there appears to be no practical limit to the size of flat circle or ring that could be Superfinished.

Shapes of Abrasives. Two shapes of abrasives are employed: square or rectangular sticks for cylindrical or cone-shaped surfaces and cup wheels for flat and spherical surfaces. Just as in grinding, the bond hardness must be chosen to accord with that of the metal. Vitrified bond is employed in much the larger percentage of cases, although a resinoid bond is sometimes used on very small diameters and in a few second operations where the best finish is desired on certain very difficult metals. For bright surfaces of 3 microinches or less rms (see Section 24, Article 9) 600 grit stones are usually employed. Where a turned surface is to be Superfinished or where a rougher finish is acceptable, stones of 120 to 500 grit are used. However, it is often surprising how good a finish can be obtained with a 320 or 400 grit stone especially in flat and spherical work.

Pressure on the stone may be applied either through spring or hydraulic means. It may vary from 10 to 40 psi of stone contact area with an average of 20, although certain high-production special machines working from turned surfaces, such as the brake drum and pressure plate Superfinishers, do operate at somewhat higher pressures and speeds than normal. Surface footage of the work is usually 30 to 90 ft per min, with an average around 55. Under these conditions of low speed and pressure, there is no perceptible creation of heat, and no "charging" with abrasive has ever been discovered.

Superfinishing Mechanism. *Cylindrical Parts.* In the Superfinishing of cylindrical parts, the essential mechanism is an arm containing a spring-loaded quill, on the end of which is mounted the stone (Fig. 7). This assembly is mounted on a base having a mechanism by which the arm and stone are oscillated, parallel to the length of the part, by a distance usually of $^3/_{16}$ in. and at a rate of 425 complete cycles per minute. Arm and base can be mounted on the cross slide of an engine lathe, as a means of rotating the work, or they can be incorporated into a machine especially designed for this purpose. If the surface is not too long (1 to 4 in., depending on the diameter), traverse will not be necessary as the stone will be the same length as the surface. The width of the stone should be approximately 75% of the part diameter. Thus, a surface 1 in. in diameter by 2 in. long should be Superfinished with a stone $^3/_4$ by $^3/_4$ by 2 in.

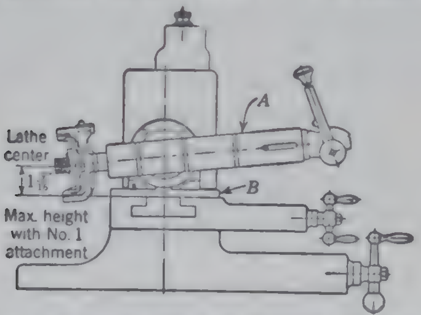

FIG. 7. Superfinishing attachment for lathe. (Courtesy of Gisholt Machine Co.)

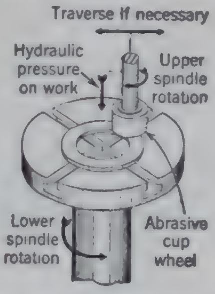

FIG. 8. Principle of flat Superfinishing. (Courtesy of Gisholt Machine Co.)

Original dressing-in of the stone is done either by drawing a strip of emery cloth back and forth between the stone face and the work or by means of a special diamond boring bar. Once properly dressed-in, the stone seldom needs any further attention. As the operation proceeds, the stone is slowly worn to the average radius of the part, which is a true and smooth curve, and it then acts as a master surface to reproduce its true geometry on the work.

Flat and spherical Superfinishing are performed with a machine containing an upper and a lower rotating spindle (Fig. 8). The upper spindle has a spring-loaded quill, on the lower end of which the cup wheel is located. The upper end of the lower spindle carries the work. (If it appears desirable, the positions of cup and work can be reversed.) As the lower spindle and work revolve, the end face of the stone in the rotating upper spindle is brought into contact with the work. Some degree of offset is given the cup with relation to the work position so that the path of any single grit is not often repeated.

When the two spindles are exactly parallel, the combined effect of the rotations of both stone and work results in the generation of a very smooth and flat surface. If the upper spindle is adjusted to some angularity with the fixed lower, a spherical shape is generated. Just as in cylindrical work, the stone automatically wears to the most desirable shape.

Finish Control. In either cylindrical or flat work, the cutting speed and finish secured are controllable in several ways. As cutting speed is increased, the quality of finish is likely to decrease. These are the means of control, in the order of their importance:

1. Decreasing the bond hardness of the stone increases cutting speed.
2. Decreasing the surface footage of the work increases the speed of cutting.
3. Decreasing the viscosity of the stone lubricant increases the speed of cutting.
4. Increasing the rate of oscillation of the stick-type stone or of the rotation of the cup wheel increases the rate of cutting.

If the quality of grinding is not rougher than 25 microinches rms, small parts are usually Superfinished in 30 seconds or less. One approximating 1 $^1/_2$ in. round by 2 in. long will be refined to 3 microinches in 1 min. Surfaces containing in excess of 20 sq in., usually requiring traverse, can be completed at a rate of 10 sq in. per min. Flat and spherical surfaces are Superfinished in somewhat shorter times than cylindrical. Tappet heads, for example, are corrected in geometry and smoothened to less than 3 microinches in no more than 30 sec.

The stock removal in Superfinishing depends on the quality of grinding also. A fairly accurate rule is that one-tenth of a thousandth of an inch will be removed from a diameter for each 10 microinches Profilometer reading of the ground surface.

Standard machines available for Superfinishing are lathe attachments for cylindrical work; several sizes of self-contained machines for cylindrical work up to 4 in. in diameter and 36 in. in length, some of which can be provided with flat attachments; a series of multispindle automatic machines for cylindrical, flat, spherical, and special parts such as brake drums and clutch plates; and a series of crankshaft machines.

31. BARREL FINISHING *

Barrel finishing, rotofinishing, or precision tumbling is basically a mechanical grinding and honing process which depends primarily on the free-mass abrasive action of special abrasive compounds, quartzite, or manufactured abrasive chips, stones, or pebbles under agitated rotary actuation. Processing may be carried out either dry or flooded with water. Grinding, deburring, removal of metal fragments left from previous machining operations, producing of predetermined radii on edges, polishing, honing, and even coloring can be readily accomplished with closely controlled results in mass production of parts.

Parts made of practically any material can be easily finished either in the hardened or the soft condition. Brass castings, forgings, stampings, spinnings, precision castings, or accurately finished machined pieces such as cams, gears, threaded units, gun mechanisms, housings, bearing rollers and cages, and rolls are among the parts normally handled. Design of parts is practically unlimited, and size may range from a few ounces to around 75 lb. Not only can removal of burrs or sharp projections be accomplished at extremely low cost per piece, but tremendous improvement in surface quality can be produced, often making it unnecessary to specify the most exacting finish possible in the primary processing operations.

Continuous wet barrel finishing is recommended and is best suited for grinding, deburring, and finishing the majority of parts. Grinding utilizes the largest chips or stones for fast cutting in eliminating burrs, fragmented metals, sharp or rough corners, and edges. Grinding also removes spinning, draw and die marks, tool marks on machined surfaces, etc. Honing action is obtained by the use of the smaller stones or chips and, naturally, results in a much finer surface finish, approaching a polish. So-called coloring, an extremely fine finishing operation using the smallest chips or in some cases highly polished hard-steel balls, is especially suited to the processing of small irregularly shaped parts.

Dry barrel finishing is somewhat limited and is used mainly for the final honing of die castings and brass castings after a preliminary fast wet grinding operation with large stones. It is also used to some extent for finishing small light-gage stampings of all metals as well as brass stampings, etc., prior to electroplating.

A wide variety of tumbling barrels are available for continuous processing. They are generally divided into five types: (1) tilting, (2) compartment horizontals, (3) tapered horizontals, (4) cylindrical horizontals, and (5) octagonal horizontals. Tilted barrels with capacities of 1 to 14 cu ft are usually lined with seasoned hardwood, and the tilting feature makes them highly economical of handling time. Compartment barrels are usually octagonal in shape and may have one to five compartments, wood lined. Capacities may run around 3 to 20 cu ft per compartment. Cast-iron tapered octagonal horizontal barrels, with capacities up to around 5 cu ft are primarily for water-rolling and sand-tumbling metal parts whose rough surfaces are to be cut down and smoothed. Cylindrical horizontal steel barrels with capacities up to about 30 cu ft are primarily for removing fins and flanges from large, heavy castings. Octagonal horizontal barrels, usually of wood with one or more screened faces, are for dry tumbling of plastics.

* Contributed by Roger W. Bolz.

Time required for processing parts varies considerably with the material, design of the part, and finish desired. Time for various metals is roughly: for machined brass, 15 min to 2 hr, for machined aluminum, 15 min to 3 hr; for cast brass, 2 to 48 hr; and for deburring steel, 1 to 8 hr. With steels, the harder the metals, the brighter the surfaces obtainable, but the longer the processing time needed. Production of simple bushings may range from 12,000 to 15,000 per hr while with more complicated parts, such as the larger ones which require a compartmented barrel, finishing time may run to several hours per part.

Commonly, the practical range of radii which can be generated on parts is 0.002 to 0.020 in., but radii up to 0.050 in. and greater have been produced. Normally, the grinding operation can be expected to produce a finish of approximately 25 microinches rms on unhardened parts, the honing operation will bring this down to about 10 microinches, and the wet coloring operation to about 3 microinches. Combinations of tumbling media can be used to radius edges and at the same time hone surface to a high quality. Finished tolerances are affected by prior processing operations, and actual cases have shown that microinch readings on parts can be reduced from 15 to about 3, from 60 to about 15, or from about 500 to 80. Surface finishes obtained in current production on aircraft engine parts such as gears, gear and spline shafts, bearing retainers, special bolts, and housings range around 6 to 8 microinches, and corner radii obtained range from 0.008 to 0.010 in. consistently.

Often, the use of barrel finishing can produce results comparable to grinding and at a much lower cost. Broached parts, for instance, originally hardened and finish ground have been tumbled once after broaching and once after hardening with extremely satisfactory finish results of 8 to 16 microinches along with smoothly finished and rounded corners. With extremely complicated machine parts, where high production rates must be met, barrel finishing serves a dual purpose in improving finish and deburring. Hand methods in such cases would present an almost unsurmountable problem.

32. POLISHING AND BUFFING

POLISHING is the removal of metal by means of a flexible wheel coated with abrasive. The wheels are made of various materials as described below. The abrasive may be any of the many forms of manufactured abrasives or natural emery. It is held to the face of the wheel by means of an adhesive, usually glue.

POLISHING WHEELS. The earliest form of polishing wheel was a wood disk with a strap of leather fastened to its circumference. This form of wheel has practically disappeared. Polishing wheels in common use are made of buff sections sewed or glued together to make a wheel of the desired face, of disks of canvas sewed or glued together, or of disks of leather, sheepskin, walrus hide, or similar material. The compress wheel is made of blocks of canvas, leather, sheepskin, paper, and other materials, compressed to the required density. The field of application and the characteristic of the several types of wheel are described below.

Clothflex wheels are made both of full disk buffs and sewed piece buffs. Both types are made with cloth of different weaves, and each type and weave have their special fields of service. Manufacturers of polishing wheels should be consulted on the selection of the grade and construction of wheel best adapted to a particular class of work.

Polishing wheels made of sewed piece buffs are used on plumbing supplies, such as faucets, tubular plumbing goods, and on brass, iron, and copper castings with contoured surfaces, and on steel stampings. They may be used on work where the corners are rounded and where it is not necessary to maintain sharp edges. They are not adapted to work where the edges of openings must be held square or where corners must not be rounded over.

The full-disk polishing wheel, i.e., made of full disk buff sections, is adapted to use on automatic machines and to work where perfect wheel balance must be maintained. Any desired density of full disk clothflex wheel may be obtained by building it of packed buff sections, that is, sections with disks of smaller diameter in between the buff disks.

Disk canvas wheels are made of disks of canvas sewed or glued together, either singly or in sections of two or three disks. Density can be varied in the same manner as with clothflex wheels by variations in sewing and gluing. The disk canvas wheel, which is adapted to heavier and rougher work than the clothflex wheel, is widely used for polishing automobile bumpers, mold boards of plows, harrow disks, etc. It is especially adapted to breaking through scale and to removing deep pits or irregularities in the surface of the work. The disk canvas wheel often is used for roughing with the coarser abrasive grains, finishing being done by a clothflex or a compress wheel coated with finer grain.

In the **compress canvas wheel,** seven densities are regularly manufactured ranging from super-soft to super-hard. The softer wheels are used for contour work or work where the surface may vary more or less from established dimensions, and a yielding wheel is necessary to adapt itself to the surface. In general, the softer densities are used in the cutlery trade, on double-header machines, for finishing large knives and on other work where the wheel must flex to cover the surface. Soft wheels should not be used under heavy pressure, as the resulting flexure of the fabric will generate sufficient heat to char the fabric.

The medium-density compress canvas wheel is a general all-round wheel largely used as a finishing wheel on such work as automobile bumper bars, sewing machine parts, hardware, automobile accessories, and similar work. It frequently is made with formed faces to fit contoured work. The harder densities of wheels are widely used in the cutlery trade for glazing cutlery and table knives. The super-hard density is used for the honing of razor blades. The selection of the proper density is highly important, a difference of even one-half grade in density often being the cause of success or failure of a wheel on a given job.

The **compress leather wheel** is used where edges and corners are to be held square and where holes are present in the work. These wheels are largely used to polish flat-iron sole plates, both for roughing and finishing, excepting the final operation which is performed with a compress canvas wheel. Compress leather wheels also are used in the cutlery trade for the finishing of knife blades.

Compress walrus and compress sheepskin wheels are used in the cutlery trade, the latter wheel giving a fine surface and good color.

POLISHING WHEEL SPEEDS. A surface speed of 7500 ft per min has commonly been used for polishing wheels working on steel, iron, or brass, and from long usage has been regarded as the most efficient speed. Some recent research, however, has demonstrated that the commonly accepted surface speed of 7500 ft per min is not necessarily the most efficient speed. A speed of 6700 ft per min in polishing medium steel showed an improvement of about 15% from the standpoint both of metal removal and time consumed. Similar results were obtained with a speed of about 7000 ft when polishing cast iron. Investigation has not been sufficiently detailed to determine whether or not these two speeds are the most efficient. It, therefore, is advisable for manufacturers polishing large quantities of metal to conduct experiments to determine the most efficient speeds for their particular conditions.

ABRASIVES. Type and size of abrasive used on polishing wheels depend on the material polished and the finish desired. Turkish emery formerly was used almost exclusively. It has been displaced by the manufactured abrasives, except as a finishing abrasive where high color is desired. For steel and brass the aluminum oxide abrasives give the highest cutting efficiency and longest wheel life. For cast iron, a silicon carbide abrasive should be used.

The size of abrasive grain to be used depends on the initial character of the surface and the finish to be produced. The first wheel should be coated with abrasive that will cut down to the bottom of the deepest pits and break through scale. The second wheel should be coated with a finer abrasive that will cut out the grain scratches made by the coarser wheel. The next wheel should have still finer grain, and so on until the desired surface has been produced. The final wheels should be greased with oil or tallow to modify the cut and to produce a more lustrous surface.

A common sequence of grain sizes for the hand lathe polishing steel is: first wheel, No. 60 or 90; second wheel, No. 90 or 120; third wheel, No. 120 or 150. If deep pits are present in the work, it may be necessary to use a coarser abrasive on the first wheel, say No. 46. It should be remembered, however, that each wheel must remove the grain scratches of the preceding wheel, and it may be more economical to use a finer wheel for a longer time to remove pits than to spend time removing coarse grain scratches. Highly polished steel is finished with a sequence of grain sizes of Nos. 60, 90, 120, 180, and 220. All the wheels finer than No. 90 should be oiled or greased. The sequence of grains may be extended even farther to produce mirror-like, scratchless surfaces. Rolls for copper and brass rolling mills have been finished with a final wheel coated with levigated alumina, which is about equivalent to a grain size of No. 640.

POLISHING WITH COATED ABRASIVE BELTS (Contributed by Behr-Manning Corp., Troy, N. Y.). As under any other method of polishing, the purpose is to remove a certain amount of material to reduce any roughness resulting from machining or previous grinding. This may be accomplished dry or with oil or grease as the situation requires.

Depending on the purpose of the operation and the selection of the proper materials, finishes on steel and many other metals may be obtained as fine as 1 or 1 $^1/_2$ rms.

Equipment. The backstand is a device which makes possible the use of coated abrasive belts in much the same way that a setup wheel would be used. It is an idler pulley mounted on a floor column or a bench base, depending on the purpose. In any case it has an attachment for tracking the belt to the center of the contact wheel and a spring or weight arrangement to maintain tension on the belt and to compensate for stretch.

The floor type is used with any standard polishing lathe or jack by mounting behind the spindle and approximately 4 ft between the center of the idler pulley and the center of the lathe spindle. This dimension is not important and may be increased or decreased according to the space available. Abrasive belts are made endless in all lengths.

The bench type may be mounted on any bench behind a bench grinder in the same manner, but the grinder should have not less than a $^1/_2$ hp motor. There are also complete units put out by several manufacturers, including motor, backstand, and contact wheel complete. These are made single and double, similar to any single or double spindle lathe, and operate one or two belts.

To complete this assembly, there must be a contact or back-up wheel mounted on the lathe spindle or bench grinder. It is over the idler pulley and the contact wheel that the abrasive belt is run, and the contact wheel provides the support for grinding.

Wheels that are acceptable for this purpose are made in a great variety but should be selected for density or flexibility, size, and construction, according to the type of work. It is obvious that any flat-faced wheel turned true and capable of supporting an abrasive belt can be used as a contact or supporting wheel, but a careful selection is necessary to obtain maximum belt life and proper flexibility.

Among the more popular wheels for belt polishing are the compressed canvas and clothflex previously described in this article. These are preferred for flat surfaces. Of the two, the compressed canvas is more expensive, but it lasts longer, holds its shape better, and offers a more controllable variety of densities. There are nine densities in all, listed from Super Hard to Super Soft and in a full range of widths and diameters.

For surfaces which diverge from the flat, that is, those which have convex curves, all such curves can be reached with a flexible abrasive belt running over a soft wheel similar to the Divine Beltflex or the Jackson Airway. These will form the abrasive belt to almost any convex curve without leaving flats or distortions.

Abrasive Belts. Abrasive cloth belts are made in two weights, "X" and "J." The X weight is used for all flat polishing and in a limited way for contour work, that is, where the surface is slightly curved, either convex or concave. For work requiring a more severe flexing, use "J" weight. This is a different type of cloth, somewhat lighter and especially flexed for use with the soft Beltflex or Jackson Airway type of wheel.

Both the foregoing types of backings are coated with either aluminum oxide or silicon carbide grain. These are considered best for all metal polishing. Aluminum oxide is preferred in all cases except for aluminum, white metal, and zinc. The standard grit numbers available in aluminum oxide are 24, 30, 36, 40, 50, 60, 80, 100, 120, 150, 180, 220, 240, 280, 320, and 400, and, except for 320 and 400, these are duplicated in the silicon carbide.

As lubricants practically any type of vegetable, mineral, or animal oil or grease may be used with coated abrasive belts.

BUFFING consists in leveling off minute projections on the surface of metal, and in producing a sheen or luster on the surface so prepared. The first operation is termed *cutting down* and the second *coloring*. The work is performed with a buffing wheel which is composed of a number of circular disks of cloth mounted on an arbor and rotated at high speed. Buffs or buffing wheels are made in several forms, each of which has its particular field of application.

Buffing wheels are made by assembling on an arbor a sufficient number of *buff sections* to form a wheel of the requisite width of face. The various forms of buff that are used are: (1) Full disk buffs, which may be either *loose* or *sewed*. (2) Sewed piece buffs, which always are sewed. (3) Some form of patented folded buff.

Buff material usually, but not always, is cotton sheeting, bleached or unbleached. The most widely used grade of sheeting has a warp of 64 threads per inch and a filling of 68 threads. It commonly is known as 64 by 68 cloth. Another widely used fabric is woven 84 by 92. Buffs made of this fabric are harder and will stand rougher usage than those made of 64 by 68 fabric. They generally are used for the cutting-down operation, the 64 by 68 buff generally being used for coloring. Buffs made of bleached material are harder than those of unbleached fabric.

Full disk buffs, made of complete disks of the fabric, are assembled in *sections*, usually of 20 plies of fabric. The loose buff is sewed with three or four closely spaced rows of sewing around the hole to hold the disks together. The sewed buff in addition to the sewing around the center hole is sewed with concentric or spiral rows of sewing, spaced at any desired interval, from the center hole to the periphery. The wider the spacing of this sewing, the more flexible and yielding is the buff.

The 64 by 68 loose buff is used for coloring soft nickel, brass, and cast iron. When sewed it may be used for cutting down copper, soft brass, zinc, and similar metals on hand lathes. The 84 by 92 buff both in sewed and loose form is used to cut down copper, brass, German silver, and heavy nickel plate on bumper bars, builders' hardware, etc. For chromium plate, it should be sewed.

Sewed Piece Buffs. The sewed piece buff is built up of more or less irregularly shaped pieces held between two full disks of fabric and sewed from the center hole to the periphery with spiral sewing. The same grades of fabric are used in sewed piece buffs of the better grades as in the full disk buffs. Many of the cheaper buffs of this sort contain much coarser and flimsier fabric. Where sewed piece buffs are purchased in large quantities, it is wise to procure them only from manufacturers who have established reputations for quality. The sewed piece buff costs less than the full disk, and for many buffing operations is equally satisfactory.

Sewed piece buffs are largely used for cutting down cast plumbing goods, brass stampings, brass tubular goods, and aluminum castings.

Folded Buffs. Folded buffs consist of full disks folded and assembled in various ways to form pockets, which then are assembled to form a complete circle and are sewed either as a loose buff or as a spirally sewed buff. These buffs are used both for cutting down and for coloring. Their action is somewhat different from that of the loose or the sewed piece buff, in that the edge of the fabric passes across the work at an angle to the plane of the buff wheel. Buff marks on the work which are produced by each separate layer of fabric in the other types of buff thus are avoided. Another advantage of the folded buff is that the pockets tend to trap air, which has a cooling effect on the buff surface. Folded buffs are relatively more expensive than any other type because of the large amount of hand labor required in their manufacture.

Buff Ventilation. Buffs continuously operating under heavy pressure must be ventilated in order to dissipate the heat generated. Without adequate ventilation the buff may char or even be set afire. Folded buffs have provision for ventilation inherent in their construction. Full disk buffs may be ventilated by the process known as *packing*. This consists in assembling one or two disks of smaller diameter than the buff disk between each pair of buff disks, or at such intervals as may be necessary, depending on the severity of the work. Sewed piece buffs can be ventilated by inserting a few disks of fabric or washers of felt or leather between each section. Packed buffs should be oscillated axially in relation to the work in order to avoid distinct streaks at the points where the disks or sections are separated by the packing.

Speed of Buffs. The surface speed at which a buff should operate depends on the type of metal being buffed. Table 8 shows the speeds commonly used with various metals and various grades of buffs. In general, higher speeds are used for cutting down than for coloring with the copper bearing metals.

Table 8. Buffing Practice for Various Metals

Material	Cutting Down					Coloring				
	Buff			Composition		Buff			Composition	
	Weave	Sewing	Surface Speed, ft per min	Kind *	Grade	Weave	Sewing	Surface Speed, ft per min	Kind *	Grade
Aluminum	84 x 92	0	8500	T	X67	64 x 68	0	7500	WD	XXX
Brass (cast)	84 x 92	0	8000	T	X67	64 x 68	0	7500	WD	XXX
	Pieced	3/8	8000	T	X67					
Bronze (cast)	84 x 92	0	8000	T	X67	64 x 68	0	7500	WD	XXX
Copper	84 x 92	0	9000	T	X67	64 x 68	0	7500	T	XX
Chromium	84 x 92	0	8000	CO	....	....	.....	....	.....	......
Monel metal	84 x 92	0	7500	C		64 x 68	0	7500	L	......
Nickel	64 x 68	0	7500	L	....	64 x 68	0	7500	L	....
Stainless steel	84 x 92	0	8500	CO	.....	84 x 92	0	8500	CO	. .
	Pieced	3/8	8500	CO						
White metal (Die cast)	Pieced	3/8	6000	T	X67	64 x 68	0	6000	WD	XXX

* C = Crocus. CO = Chromium oxide. L = Lime. T = Tripoli. WD = White diamond.

Since a buff wears down in use, its peripheral speed constantly decreases. Provision should be made to maintain the peripheral speed fairly constant either by the provision of a variable-speed drive or by changing the buff to a machine of higher spindle speed for each decrease of 2 in. diameter.

Pressure and Horsepower for Buffing. The effectiveness of buffing depends largely on the pressure of the wheel on the work. Increasing the pressure increases the rapidity of cutting, but at the same time increases the liability of cutting through the plating on plated articles. Definite rules cannot be given since the pressure that can be safely applied depends on the hardness of the plating and its thickness. A heavy coat of hard nickel can withstand much greater pressure than a thin coat of soft nickel. The horsepower required for buffing is a function of the pressure of the wheel on the work. In general, for buffing nickel plate on steel on hand lathes 3 to 5 hp at the buff is the usual practice. For heavy work, such as automobile bumper bars, hand lathes usually are equipped with 10- to 15-hp motors.

Brass requires considerably more horsepower for buffing than steel or nickel. Experiments indicated that a pressure of 15 lb per in. of width is required for cutting down sheet brass, and 10 lb per in. of width is required for coloring.

Buffing Compositions. The following compositions are adapted to the different varieties of work: for cutting down brass, bronze and Britannia metal preparatory to plating, tripoli; for smooth surfaces on nickel and brass, crocus; for coloring brass, copper, nickel, bronze, German silver, etc., either in solid or plated metal, White Diamond XXX composition; for chased or embossed parts, or for cutting down silver-plated pieces which are afterward to be colored with rouge and alcohol, White Diamond XXXX composition is used; for nickel-plated pieces with a high luster, Vienna lime. Where rapid, sharp, even cutting is desired, emery cake is used. Chandelier rouge is used to produce a deep color on brass and bronze parts. Chromium oxide is used for chromium-plated articles and stainless steel.

POLISHING AND BUFFING MACHINERY. For irregularly shaped pieces, or where work is performed in relatively small lots, the hand lathe is almost universally used both for polishing and buffing. For long runs of similar work, automatic or semi-automatic polishing and buffing machines are advisable. They are economical of labor, have high capacity, and produce uniform work. In one instance, automatic equipment reduced the number employed on a given line of work from 31 to 5 operators, increasing production at the same time. Automatic machines for automobile bumpers have been built with an output of upwards of 300 sets of bumpers per hour. Automatic machines may be divided generally into three classes, straight-line machines, multiple-head machines, and contour machines.

Straight-line machines comprise essentially a conveyor on which the work is carried in appropriate chucks or holders underneath a series of polishing wheels, successively coated with the various sizes of grain necessary to obtain the desired finish. The wheels are arranged to float, either on an arm oscillating vertically on a horizontal shaft or between vertical guides. Each wheel is driven by an independent motor, direct-connected to the wheel spindle or driving the wheel spindle through V belts. The conveyor is driven by an independent motor. The more common form of conveyor is a belt, although various other forms embodying roller chain, or other construction, have been built. The conveyor usually is driven through a speed changing device at speeds ranging from 15 to 35 ft per min.

Multiple-head Machines. Multiple-head machines are used principally for the finishing of circular work. In their simplest form they consist of a head carrying two spindles on which chucks are mounted to hold the work. The head is indexed by hand to bring the work on each spindle in contact with the polishing or buffing wheel. The spindle in the working position is rotated by a small motor mounted on the machine. The idle spindle is unloaded and reloaded during the operating time of the working spindle.

Contour machines for polishing or buffing articles of rectangular outline, or forms not truly circular, are essentially a rotating spindle which carries the work, combined with a mechanical movement which causes the work to approach or recede from the wheel in conformity with the contour, and maintains uniform contact of the work and wheel at all times. The mechanical movement may be a cam of appropriate shape or a geared chuck.

Special machines have been built for many different purposes including the finishing of ice-skate blades, windshield wipers, blank book backs, sewing thimbles, tubing, sheet and strip metal, heads of screws and bolts, and various forms of cutlery. Some of these machines employ polishing wheels in pairs, the work passing between the wheels in order to finish two sides at one operation.

Principles for Polishing and Buffing Machine Design. The following principles should be embodied in polishing machines. (1) *Variable Wheel Speed.* Where a machine is to be used with wheels of a variety of diameters, or where the diameter decreases in service, as with a buffing wheel, provision should be made for a variable-speed wheel spindle. Wheel speed then may be maintained constant at the most efficient point. (2) *Variable Work Speed.* Provision should be made to vary the speed at which the work moves past the wheel. The time required for a wheel to do its work varies with different materials, and provision should be made to change the work speed as necessary. Work speeds range from 200 ft per min with strip zinc, to 15 ft per min with stainless steel. Hardness of material and character of finish desired also influence work speed. (3) *Variable Wheel Pressure.* Excessive pressure of the wheel on the work may damage the wheel and work, change the character of the finish, and increase the cost of polishing or buffing. Hence all machines should have provision to regulate wheel pressure. (4) *Wheel oscillation* in an axial direction is desirable to avoid deep scratches and wheel marks. (5) *Vibration* should be eliminated by adequate foundations, sufficient weight in machine bases, shafts of adequate diameter, ample bearings, and dynamic balance of rotating parts. Machine vibration will spoil finished surfaces and increase costs. (6) *Work-holding fixtures* of such design as to properly present work to the wheel, and to facilitate rapid loading and unloading, greatly reduce the cost of machine operation.

For many data on the design and operation of polishing and buffing machines, see Ref. 10.

BROACHING

By Roger W. Bolz

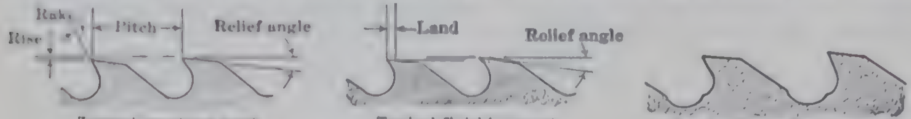
During the last quarter century broaching has risen from a relatively unknown production process to one of major importance in present-day mass-production manufacturing. The rise of broaching into industrial prominence is due primarily to its two salient characteristics—extremely high speed of production, which makes possible minimum cost per piece of parts suited to broaching, and high repetitive accuracy.

Although broaching is recognized principally for its value as a production method suitable for manufacture at extremely high rates of output, it is now being applied to considerable advantage in even medium-volume production work where rather large lots of 2500 to 5000 pieces can be run. Where multiple jobs can be tooled up to run in succession to make up such quantity lots, relatively smaller quantities of certain parts can thus be designed to obtain the benefits of broaching. Cases are on record where as many as twelve different setups are used in this manner.

33. THE BROACHING TOOL

Developed from so-called drifts almost a century ago, broaches were first used to cut keyways and were driven through the part by means of a hammer. Round holes followed later, and by the turn of the century surface broaching was in limited use. Today, holes of any cross section from plain round or oval to inverted or helical spline can be readily produced to exacting tolerances. Over and above a wide variety of flat, related flat, or flat and curved surfaces, compound shapes such as gear teeth, chain sprocket teeth, sinuous slots, and turbine blades comprise an ever-broadening field of possibilities for economical production. The principal limitation of the process, however, must be observed in judging the advantages of broaching or in designing specific parts for such production. Owing to the necessity for each tooth gullet of a broach to retain the chip created until the entire pass across the part is completed, the process is not particularly suited for removing large amounts of material. Stock removed per tooth and length of broach must be economically balanced to achieve optimum results.

THE BROACH. Unlike turning, milling, shaping, planing, or similar tools on which the most favorable operating conditions can be secured by simple adjustments in feed or speed, a broach has a predetermined fixed feed or cut represented by the rise in height of each tooth (Fig. 1). This, of course, is usually established by the broaching tool designer but also must be recognized in designing parts to be broached in order to assure the most practical and economical manufacture.



Typical roughing tooth

Typical finishing tooth

Special Foote-Burt patent tooth form for heavy cuts

FIG. 1. Broaching tooth form.

Because each tooth gullet of a broach must retain the chip created until the tooth has finished the cut, obvious limitations are present in broaching tool design (Fig. 2). Depth of cut or rise per tooth is thus broadly restricted by the practical size of gullet allowable between teeth. Size of tooth gullet, of course, is directly related to tooth size or pitch, tooth depth usually ranging around one-third the pitch or slightly greater. As a rule, a minimum of two teeth should be cutting at all times, and preferably three; a minimum of three teeth per inch is recommended for parts having a length of 1 in. or less.

Desirable tooth pitch, and therefore chip thickness, is further restricted or controlled by machine power available and tooth strength. Internal or hole broaches of the pull type are limited by the strength of the tool itself, and this can be calculated from the following formula normally employed:

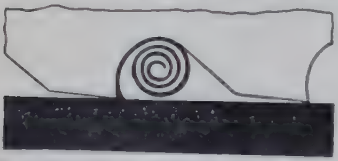


FIG. 2. Correct chip formation in broaching.

$$P = \frac{AT}{S} \tag{1}$$

where P = allowable pull, pounds per square inch; A = area of the minimum section which occurs at the root of the first roughing tooth or at the pull end, square inches; T = tensile strength of the broach material, pounds per square inch; and S = factor of safety to prevent broach damage because of sudden overloads due to hard spots in material, etc. Minimum tooth pitch, as can readily be seen, will help attain maximum broach strength and life.

In push broaches length is a critical factor, and the tendency is for the tool to buckle in the center, usually the weakest point. When L/D is greater than 25, a push broach is considered as a long column, and strength in this case is computed as

$$P = 13{,}500{,}000 \times D^4/SL^2 \tag{2}$$

where P = allowable push, pounds per square inch; D = root diameter of broach at $^1/_2\,L$, square inches; L = length of broach from push end to first cutting tooth; and S = factor of safety. When ratio of L/D is less than 25, a broach is considered to act as a short column which resists straight compression loads only, and, as a rule, broaching loads are not critical for a tool of these proportions.

Length of broach which can be used for internal pull broaching depends on the machine stroke available. Economy, however, dictates the shortest possible tool for the job. Reasonable length-to-diameter ratio also dictates the shortest possible tool to assure adequate stiffness in broaching and sharpening. Standard machines available have strokes up to 66 in. and are capable of handling broaches up to 62 in. in length. Larger machines are in use, however, and some standard broaches available run up to as much as 74 in. in length; for special jobs such as rifling, even much longer tools are used.

MATERIAL REMOVAL. Tool strength in surface broaching is not the critical factor. Machine capacity, however, is, and again relates back to tooth pitch and rise inasmuch as volume of material removed is limited by both stroke and power. The total amount of material which can be removed for each available ton of ram pressure per foot of stroke is 0.06 cu in. for cast iron, 0.04 cu in. for medium-hard steel, and 0.03 cu in. for tough alloy steels having Rockwell hardness over C28. In Table 1, the relationship between tooth pitch and chip area is correlated for the various commonly used pitches. Since these chip area figures represent the product of chip thickness and lengths of cut, the maximum stock removal for any size part can be approximated for any machine available.

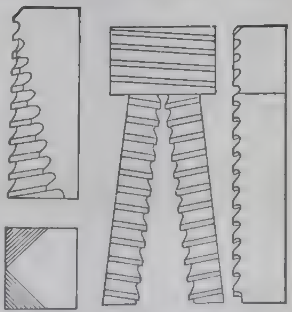
Table 1. Relationship of Tooth Pitch and Chip Area per Tooth *

(Courtesy of Cincinnati Milling Machine Co.)

Pitch of Broach Teeth, in.	Chip Area for Steel, sq in.	Chip Area for Cast Iron, sq in.
0.2500	.0014	.0028
0.3125	.0022	.0044
0.3750	.0031	.0062
0.4375	.0042	.0084
0.5000	.0055	.0110
0.5625	.0070	.0140
0.6250	.0086	.0172
0.6875	.0104	.0208
0.7500	.0124	.0248
0.8125	.0145	.0290
0.8750	.0168	.0336
0.9375	.0193	.0386
1.0000	.0220	.0440
1.2500	.0330	.0660
1.5000	.0495	.0950
1.7500	.0673	.1346
2.0000	.0880	.1760

* Chip thickness times length

Material removal in single-pass broaching thus is usually limited to a maximum of about $1/2$ in. or less in thickness, depending to a large extent on the capacity of the machine to be used. Standard machines, as noted previously, allow for up to 62 in. of broach; continuous machines run up to 90 in. standard and specials have been made carrying up to 120 in. Normally, surface broaches are made in sections of 6 to 15 in. in length primarily for economy, but special sections such as for gear teeth are made longer. Where amounts exceeding the removal capacity or stroke of the machine are necessary, repetitive or multiple-stroke cuts must be made. Rise or cut per tooth can be made heavy if desirable by ingenious broach design. Staggering of the cutting portions of each tooth so as to achieve complete overlap over the entire surface or hole often can be employed to keep the total of the material being removed at any instant well within machine horsepower. This method is widely used in surface broaching as the "progressive" broach (Fig. 3).



Progressive one-piece **Progressive sectional**

Fig. 3. Progressive broaches.

DATA NEEDED FOR BROACH DESIGN. General information requested by broaching tool manufacturers in order to design a successful broach is as follows: (1) Drawing of part giving tolerances. (2) Material specifications including prior heat treatments, hardness, and whether cast, forged, cold rolled, etc. (3) Prior machining operations, including machined locating surfaces if provided. (4) Subsequent heat treatment which may affect accuracy of broached dimensions through shrinkage, warpage, etc. (5) Production quantities and production rate. (6) Finish quality desired. (7) Broaching machine to be used, including maximum and minimum stroke, power capacity in pounds of pull or push, and details of broach support fixtures, shank type required with length to first tooth, and type of puller. In addition, for hole broaching: (8) Dimensions and shape of hole before broaching including length of hole and how prepared—whether drilled, reamed, hot or cold punched, forged, or cored. (9) If recesses or counterbores are used, state whether machined before or after broaching. (10) Whether more than one hole is to be broached at one time. In relation to splines: (11) If hole is to be ground after broaching, give stock allowance for grinding. (12) Radius or chamfer desired at ID and OD. (13) Whether broach is to size ID as well as cut splines and concentricity of splines with ID. (14) Spline fit and how controlled. (15) All gear elements for involute forms and lead and helix angle if required. For keyways: (16) Guide to be used. (17) Relation of keyway to other dimensions. For surface broaches: (18) Method of holding part. (19) Length and width of cut. (20) Maximum stock removal. (21) Total number of surfaces or parts to be completed at once. (22) Design of broach holder.

BROACHING TOOTH DESIGN. **Pitch** is determined primarily by length of cut and thickness of chip removed per tooth, consideration being given to type and condition of material to be broached. Formula sometimes used to estimate approximate tooth spacing for round broaches is $P = 0.35L$, where P = tooth pitch, inches; and L = length of cut to be made. Actual pitch used must be modified to suit necessary chip gullet capacity (Table 1).

Gullet. Area of gullet space should be ten times the cross-sectional area of the chip for steels, and five times for noncontinuous chip materials such as cast iron (Table 1).

Rise per Tooth. In free-machining steel this is usually 0.0015 to 0.003 in. for round broaching, 0.004 to 0.006 in. for spline, 0.001 to 0.006 in. for keyway and surface broaching. Practical minimum rise is about 0.00025 in. Rise per tooth as high as 0.015 in. can be used on narrow trimming broaches, where the cut is across the piece and the chip need not be contained in the tooth gullet. Slotting broaches should not exceed 0.00275 in. rise to avoid jamming of heavier chips against the sides of the slots. Preferable rise is 0.0025 in. Values can often be doubled for cast iron, malleable iron, and brass. For burnishing or sizing, rise per tooth is not over 0.001 in. and often 0.0001 in. or less.

Rake Angle. Rake angle, sometimes termed face angle, varies with the material and its condition. It is usually 6 to 8 degrees positive for cast iron; 8 to 12 degrees positive for hard steel, 15 to 20 degrees positive for soft steel, approximately 10 degrees positive for aluminum, and 5 degrees positive to 5 degrees negative for brittle brasses.

Relief Angle. Normally this angle falls between 1/2 and 3 degrees for internal broaches and is up to 3 1/2 degrees for surface broaches. For steel, the relief angle may vary from 1/2 to 2 degrees; for cast iron, from 2 to 5 degrees; and for brasses and bronzes, from 1/4 to 1/2 degree. Relief may vary from maximum at one end to minimum at the finishing end to minimize loss of size in resharpening.

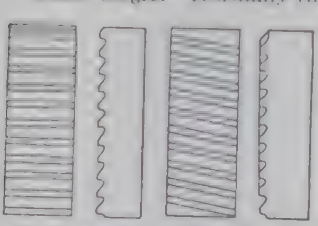


FIG. 4. Straight and shear cut broaching teeth.

Land. Varies from zero to 1/16 in. in width and is usually graduated in width from the first finishing tooth to the last on internal broaches. Often calculated as 0.2 of the pitch. The land varies from zero to 0.005 in. for surface broaches and is usually backed off about 1/4 degree.

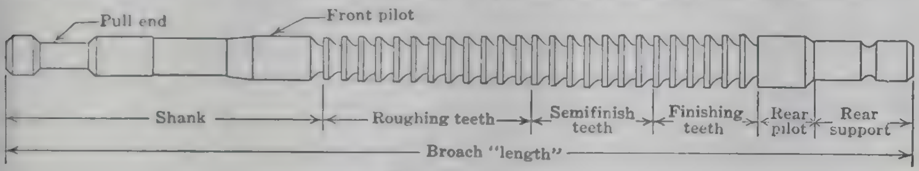
Shear Angle. Shear cutting teeth (Fig. 4) are used wherever possible to obviate chatter and improve finish. Should not be used on deep slotting. Angle of teeth relative to direction of cut is usually 5 to 20 degrees. Minimum angle with surface broaching is usually 15 degrees.

34. THE BROACHING PROCESS

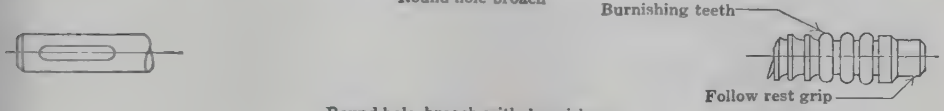
BROACHING SPEEDS. Cutting speed or travel of a broach across the work is usually fifteen to twenty-five times faster than in milling. Steel castings and forgings are normally broached at speeds of 20 to 33 ft per min whereas cast iron, brass, or aluminum are often broached at speeds up to 40 ft per min. While brass and aluminum can be satisfactorily cut at speeds even as high as 80 ft per min, most modern broaching machines have a much lower maximum ram travel, the fastest of which is about 43 ft per min. Faster speeds normally are found impracticable owing to lack of sufficient time for fixture loading and unloading. In the high-production manufacture of locks, however, broaching speeds as high as 59 ft per min are used to cut the narrow sinuous key slots in brass.

BROACHING MACHINES. There are two broad classes of broaching machines available for performing almost any variety of broaching operations, the vertical and the horizontal, either of which may have one or more rams. Although most modern machines are hydraulically driven, a few are operated mechanically. Plain horizontal machines are usually of the pull type, but vertical machines are available as pull-up, pull-down, or push-down types. Most of these machines can be arranged for efficient production of the quantities required and where necessary semi-automatic operation can be employed. Where extremely large quantities are in view as in some automotive and similar work, continuous broaching is a possibility. In these machines the broaches are stationary, a continuous chain conveyor with fixtures carrying the work pieces past the broaches. Other special machines such as for broaching radial surfaces are also in use.

ROUND PULL BROACHING. This method is used for producing holes of high accuracy and fine finish (Fig. 5). Holes may be finish broached from drilled, reamed, bored, cored, punched, or hot-pierced holes. Starting hole size should be $^1/_{32}$ in. smaller than the finished hole for small diameters, increasing to as much as $^1/_{16}$ in. smaller on large diameters. To assure clean-up and good finish, the allowance on diameter should never be less than $^1/_{64}$ in. Where cored holes are planned, draft angle and size variations must be taken into consideration to assure entry of the pilot and good clean-up. If extremely smooth finish is necessary, burnishing teeth or buttons can be used at the end of the tool (Fig. 5). However, these are recommended only for cast iron and nonferrous materials. Long holes should be avoided or chambered to reduce the length of broach required.



Round hole broach



Round hole broach with burnishers

FIG. 5. Round pull broach design.

ROUND PUSH BROACHING. Employed to produce the same results as pull broaching, this method usually is restricted to parts requiring a relatively small amount of stock removal, since the tool must be comparatively short in order to have adequate stiffness to withstand the force exerted by the press ram. Push broaches are used for sizing holes after drilling, reaming or pull broaching round or splined holes, and for smoothing of die-cast and similarly produced holes. Special sizing broaches can be used for removing scale and correcting distortion in the holes of hardened gears, correcting errors in spacing of splines, correcting distortion in splines, etc. Push broaches are widely used for forming or sizing "blind" holes through which the tool cannot be completely passed. To prevent the cutting teeth from dragging on the return stroke, burnishing buttons are sometimes used to open the hole slightly.

BURNISHING. A cold-working operation, burnishing removes no metal but only compresses and smoothes out fine surface irregularities. Contraction usually follows the expansion of a hole produced by burnishing. Amount of contraction varies with the material, size of the hole, and construction of the part and can be determined most easily by experiment. Only soft, ductile materials are well suited to the burnishing operation. Burnishers are usually short and consequently are pushed through the hole.

REGULAR AND IRREGULAR-SHAPED HOLE BROACHING. This phase of the process is similar to round push and pull broaching. Symmetrical internal shapes usually are started from drilled, punched, or cored holes. The method of generating a square hole is illustrated in Fig. 6. However, where possible, an oversize starting hole should be used to make possible a shorter, more economical tool and much faster production. Because a broach is a form-generating tool, irregular holes of all varieties may be produced within the previously mentioned metal removal capacity.

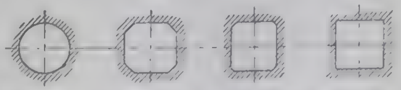


FIG. 6. Generation of a square hole by broaching a round hole.

KEYWAY, SLOTTING, AND CUTOFF BROACHING. Broaches for this type of work may be push or pull variety and can be used for producing single plain keyways, multiple plain splines by means of indexing fixtures, or for finishing round holes simultaneously with a plain keyway. A keyway-type broach is also adaptable for sawing or cutoff work and also is useful in producing various slot designs, especially where very narrow or sinuous key slots are required to exacting dimensions. Effectiveness of coolant action with this type of tool obviates heat distortion troubles otherwise present in such thin-bladed tools. Rise per tooth usually is restricted to a maximum of 0.00275 in. to avoid marking or scoring of the slot sides by the spreading action of chips formed with heavier cuts. This limits the depth of slot to about $^7/_{16}$ in. on a 66-in. capacity standard machine. Slots $^5/_8$ to $^3/_4$ in. deep are possible on 120-in. machines.

MULTIPLE-SPLINE SERRATION AND GEAR BROACHING. Splines of any required shape can be broached and are usually generated rather than cut directly. Both straight and spiral splines are produced having straight, involute, angular-sided, radius-lobe, and inverted shapes, Fig. 7. Broaches are usually of the pull type owing to length of tool necessary for removing the large quantity of material. As a rule the work is first drilled, bored, broached, or reamed to proper minor diameter and then broached, cutting the splines only. Where high concentricity is desired between the splines and the inside diameter, the hole can be prepared as for round broaching and a combination round-and-spline broach employed to finish the inside diameter as well as the splines. This type of tool is particularly useful on high-production jobs requiring extreme accuracy. Present practice is to size the inside diameter with the broaching tool when producing involute splines.

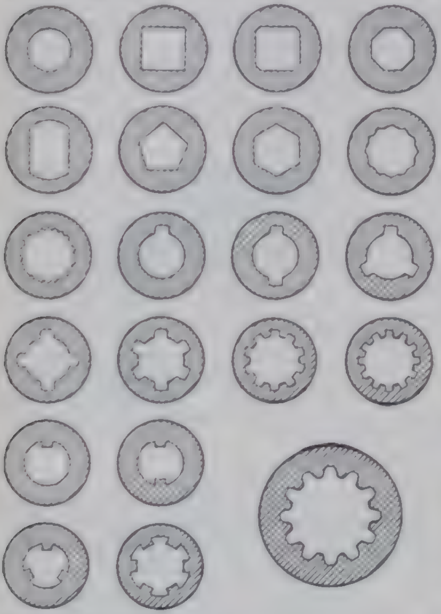

Fig. 7. Typical internal broaching. (Courtesy of Illinois Tool Co.)

Spiral-spline broaches generate tooth shape in much the same manner as straight-spline broaches. Where the helix angle of the spiral is less than 15 degrees and preferably under 8 degrees, it is possible to pull the tool through the part with a ball-bearing puller, the broach itself revolving to generate the proper helix. If the angle is larger than 15 degrees, a lead screw is necessary to assure positive and accurate generation. It is not usually practical to broach splines with a helix angle greater than 60 degrees.

Involute spline or **internal-gear** broaches, which can be made to cut any number of teeth, are used for producing spur or helical gears with teeth as small as 48 diametral pitch. In these gears the involute form is generated and checked from the base diameter. For extremely accurate parts or those heat treated after the first cut, a sizing or finishing operation should be used.

Serration broaches, similar to spline broaches, are usually made to SAE standards although, of course, special designs can be made to suit. Sizes range from $^1/_8$- to 3-in. nominal diameters with 36 to 48 serrations and may be tapered or straight. Serration drifts are used to produce taper serrations after broaching with a straight serration broach. A combination push broach and taper drift can be employed in some cases.

SURFACE BROACHING. A fast, accurate method for producing flat, curved, or irregular surfaces, this method of broaching is unexcelled for making a relatively smooth, even finish at low cost. One of the many combinations of tools available usually can be adapted to suit the job on hand. Gear segments, racks, serrations of any variety, slots, teeth, curved guides, etc., can be machined at one pass with exceptionally accurate relationship between the various surfaces. Typical procedure for surface broaching a connecting-rod forging is shown in Fig. 8. Removal of the surface skin on such forgings relieves certain internal stresses which in turn cause the bore to open up slightly. A boring operation is necessary after broaching such a cap and rod to assure a perfectly circular bearing seat. For best economy, surface areas should be kept to a bare minimum.

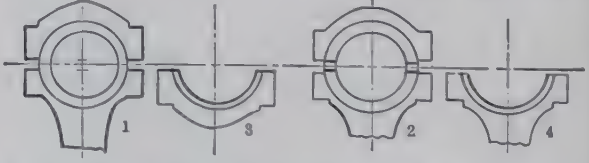

Fig. 8. Progressive stations for broaching a one-piece connecting-rod forging. (Courtesy of Foote-Burt Co.)

CONTINUOUS BROACHING. The various types of hole broaching require a definite cycle for starting the broaching tool through the hole and returning to starting position after a cut; and even considering automatic broach handling turret type verticals, production output of the continuous surface broaching method is unexcelled. A wide variety of plain or irregular surfaces, so long as they are parallel on the part, can be machined by this method and particularly those parts which require a series of such related surfaces. Fixtures can be designed to index one or more times as the part passes through the stationary broaches to produce squares, hexagons, slots, bevel gears, and similar forms on a single pass through the machine. Table 2 gives actual figures concerning current practice on the various parts shown in Fig. 9, produced on both regular and continuous machines.

Table 2. Production Data on Typical Broached Parts

(Courtesy of Foote-Burt Co.)

No. *	Part	Operation	Material	Broaching Machine	Pieces per hr	Pieces per grind
1	Connecting rod and cap	Broach sides, back of bolt bosses, partial splitting, final splitting, joint faces, and half round rod and cap	SAE 1035 steel forging	15-ton, 66-in. stroke duplex vertical hydraulic surface	120 sets	20,000 to 25,000
2	Fuse body	Broach tongue, top of tongue, wrench slots, and chamfer tongue	SAE 1112 steel	No. 15 continuous horizontal surface	1200	45,000 to 60,000
3	Drive end expander	Broach 0.230 x 0.375 deep slot and radius edges	SAE 1112 steel	No. 10 continuous horizontal surface	2200	35,000 to 40,000
4	Fuel pump rocker arm	Broach 0.317 x 0.812 deep slot	SAE 1115 steel forging	No. 15 continuous horizontal surface	1200	......
5	Connecting rod and cap	Broach sides, back of bolt bosses, split, joint faces, and half round rod and cap	Cast iron	No. 5 and No. 10 continuous horizontal surface	600 sets	......

*See Fig. 9.

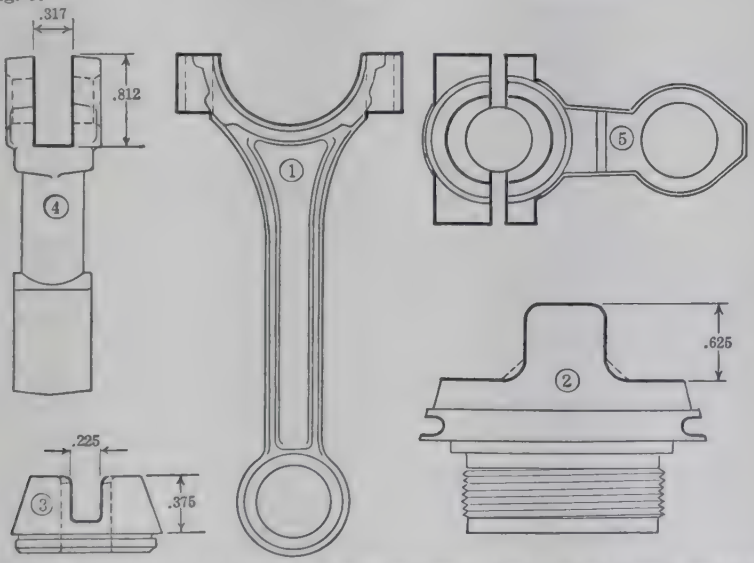

FIG. 9. Typical surface-broached machine parts. Production data relating to each part are given in Table 2. (Courtesy of Foote-Burt Co.)

MATERIALS. Any material that can be machined can be broached, but for the most practical and economical results hardness should range between Rockwell C25 to C35. Harder materials involve additional wear, and softer ones tend to tear. In any case, hardness should be rather carefully controlled to prevent excessive variation because such variation often results in poor surface finish. Internal stresses due to heat treatment should be avoided in parts which must be accurate because the relief of such stresses in broaching results in warpage.

TOLERANCES. Close accuracy and uniformity in surface broaching depend to a large extent on heavy, rigid fixtures, and a solid machine slide having a minimum of deflection. Internal broaching accuracy, however, is dependent more on uniformity of material. Holes can be held to within ±0.0005 to 0.001 in. in production. Plain splined holes can be held to +0.001 in., −0.000 in. on the major and minor diameters with width of splines within ±0.001 in. Outside diameter of serrations and diameter measured over wires can also be held to +0.001-inch, −0.000 in. Closer limits can be held if cost warrants and standard involute splines are normally held to +0.0007 in., −0.0000 in. on major diameter and +0.0015 in., −0.0000 in. on minor diameter.

In surface work, straddle-broached faces can be held to ±0.001 in. but, where design demands, plus or minus one quarter-thousandth can be obtained. Slots can be held to ±0.0002 in., but ±0.002 in. are the normal economical limits. Spacings of lugs, straddle-broached, can be held to 0.0003-in. accuracy. External gears and racks, broached one tooth at a time, can be held to 0.0005 in. on tooth spacing and form. On high-production runs where the entire segment is completed in one pass, even closer tolerances can be held. On large chain sprockets, tooth form and spacing can be held to ±0.005 in.

Manufacturers. Broaching machines are built by American Broach & Machine Co., Ann Arbor, Mich., Cincinnati Milling Machine Co., Cincinnati, Ohio; Foote-Burt Co., Cleveland, Ohio; LaPointe Machine Tool Co., Hudson, Mass.; Colonial Broach Co., Detroit, Mich.; Oilgear Co., Milwaukee, Wis.; Acme Broach Co., Lexington, Ky.; Zagar Tool Co., Cleveland, Ohio.

METAL SAWING

By W. T. Gloor

The generally used methods of sawing metals are: (1) **Hack saws,** of which there are two types: (a) *hand hack saws* for occasional use at a bench, on assembly work, and in the field, (b) *power hack saws* for cut-off of light, medium, and large sections in production work. (2) **Band saws,** of which there are three types: (a) *contour saws* for sawing irregular designs, (b) *metal cutting band saws* for production cut-off of light and medium sections; (c) *friction saws* for sawing light sections and harder materials. (3) **Metal-cutting circular saws,** of which there are two types: (a) *milling saws* for slitting and slotting operations in manufacturing, (b) *cut-off saws* for production work on light, medium, and heavy sections. (4) **Friction disks** for cut-off of medium and heavy sections in either the hot or cold condition. (5) **Abrasive disks** for cut-off of light and medium sections in production work.

35. HACK SAWS AND BAND SAWS

HACK SAW BLADES are generally made of high-speed steel, though semihigh-speed steel blades find a moderate use and carbon steel blades a very limited use in present-day production. *Hand hack saw blades* are available in full hard, soft back, spring back, and double edge, with the spring back blades finding increased use because of low breakage and yet good cutting qualities. *Power hack saw blades* are either of the full hard or the spring back types. The saw teeth have various tooth shapes and are arranged on the blade to cut in one direction only. The teeth generally have no rake angle and are "set" in several patterns to provide clearance for the chips removed by the cutting action as well as the back of the blade. Table 1 gives data on standard high-speed steel blades.

Table 1. Dimensions and Teeth of High-speed Steel Hack Saw Blades

	Hand Saws		Power Saws													
Length, in.	10	12	12		14			17			18		21	24
Width, in.	9/16	9/16	1	1	1	1	1 1/4	1	1	1 1/4	1	1 1/4	1 1/2	1 1/2
Thickness, in.	.025	.025	.049	.065	.049	.065	.065	.049	.065	.065	.065	.065	.065	.065
Teeth per in.														
Regular	18	18	.....	.....	.....	.....	4	.....	.....	4	.....	4	4	.....
Medium	24	24	.....	6	.....	6	6	.....	6	6	.....	6	6	6
Fine	32	32	.....	10	.....	10	10	.....	10	10	10	.....	10	10
Tubing	.....	.....	14	.....	14	.....	.....	14	.....	.....	.....	.....	.....	.....

These are the fields of the several classes of teeth: *Regular*—soft steel, cast iron, bronze. *Medium*—annealed high-carbon steel, high-speed steel. *Fine*—solid brass, iron pipe, heavy tubing. *Tubing*—thin tubing, sheet metals. It is advisable to use finer teeth for the sawing of thin sections or hard materials, whereas coarser teeth are more advantageously used for sawing thick sections or soft materials. To avoid possible stripping of the teeth from hack saw blades, it is recommended that two or more teeth be in contact with the work wherever possible.

The approximate sawing speeds in feet per minute for high-speed steel saw blades are shown in Table 2.

Coolant aids in decreasing sawing time and increasing blade life for ferrous materials as well as nonferrous materials. No coolant is required in the sawing of cast iron, brass, magnesium, and a few other exceptions.

Table 2. Cutting Speeds for High-speed Steel Hack Saw Blades

Material	Range of Speed, sfpm
Brass	160–200
Cast iron, gray	60–80
Steel, mild	140–180
Steel, tool, annealed	100–120
Steel, stainless	100–120
Rails	60–100
Steel, nickel	80–120
Phosphor-bronze	160–200

HACK SAW MACHINES, or power hack saws, range in capacity from stock 4 in. square up to stock 18 in. square. One type, built with a gap frame, can cut stock 16 by 26 in. by turning the work over when sawed halfway through. The stroke of the saw is 4 in. in the smaller machines and 9 in. in the larger machines, though this varies with manufacturers. All machines lift the saw clear of the cut on the return stroke, thus eliminating tooth drag and wear. Some machines feed by gravity, the saw frame being provided with weights that can be shifted to give greater or less pressure on the saw as required. Other machines have a positive feed which ranges from 0.001 to 0.025 in. per stroke, depending on the class of material being cut. When hard spots are encountered the automatic feed is stopped or shortened to decrease the cutting pressure on the saw until the hard spot has been cut through. Hydraulically operated machines in general provide variable cutting pressures and greater versatility. Automatic stock feeds have been adapted to a number of machines where numbers of pieces are to be cut off. Hack saws for making miter cuts are available in both the small and large capacities. Hack saws are powered either by belt or by a motor within the base. Generally three stroke speeds are supplied, and the amount of stroke is adjustable to suit the class of work.

METAL CUTTING BAND SAWS are used in production for cutting all types of materials up to a 12-in. square. Essential to the efficient cutting of a band saw is the proper adjustment of the pulley for alignment and tension. The saw blade is made in widths of $^1/_2$ to 3 in., depending on the class of work to be cut. The generally recommended sawing speeds, in feet per minute are: Aluminum—1000–1500. Brass—soft castings 500–700, hard castings 150–300, sheets 750–1500, tubes 750–1500. Cast iron—100–150. High-speed steel—100–125. Cold-rolled steel—150–200. Malleable iron—150–200.

Machines manufactured for this use are of either vertical or horizontal type. Generally the vertical type is used in the cutting of sheets of material, and the work is fed into the blade. The horizontal type is used for cut-off of stock, and in this case the band saw blade is fed through the rigidly clamped work, usually by a power feed. Band saws are built with a variety of speeds to allow a range of material to be cut. They are also used in removing sprues, risers, and gates from castings.

CONTOUR BAND SAWS are similar to the general metal cutting band saws in method, but differ in the width of blade used. Contour saws vary from $^1/_{16}$ to $^1/_2$ in. in width up to 1 in. and are generally of an alloy steel. Table 3 shows the proper width of saw blade to be used in cutting radii.

Table 3. Minimum Radii for Contour Saws

Contour Saw Width, in.	Minimum Radii Heavy Set Saws
$^1/_{16}$	90 degrees
$^3/_{32}$	$^1/_{16}$ in.
$^1/_8$	$^1/_8$ in.
$^3/_{16}$	$^5/_{16}$ in.
$^1/_4$	$^5/_8$ in.
$^5/_{16}$	1 in.
$^3/_8$	1 $^7/_{16}$ in.
$^1/_2$	2 $^1/_2$ in.

Sawing speeds are somewhat dependent on the class of work to be cut, which determines the width of the contour saw. The thickness of contour saws falls in the range of 0.025 to 0.040 in. For saw widths of $^1/_{16}$ to $^1/_4$ in. the following cutting speeds in feet per minute are recommended. Aluminum—forged or dural, 1000–1500. Brass—cast 500–1000, naval (rolled) 250–350. Carbon steel—200–300. Steels—chromium 120–150, stainless 75–100, high speed 120–150. Malleable iron 180–220. For wider contour saws the cutting speeds are reduced. *Machines* used in contour sawing are of the vertical type with a deep throat and a speed range to cover a variety of work. A resistance welding unit is built into the machine to rejoin the saw when a central portion is being cut out of a piece.

FRICTION BAND SAWS are applicable to cutting single sheets or shapes. Sawing speeds used are in the range of 3000 to 15,000 surface feet per minute. A burr is generally left on the under side of the work. Feed rates of 25 to 60 in. per minute are recommended for material less than $^1/_4$ in. thick, with a range of 5 to 25 in. per minute for $^1/_2$-in. thick material. Heavier materials require greater care. The method is recommended for ferrous materials such as stainless, armor plate, etc., and for tool salvage. However, the method is not applicable to materials of low melting point or to those having a high thermal conductivity, e.g., aluminum, magnesium, brass, copper.

36. CIRCULAR SAWS AND FRICTION DISKS

Circular saws fall into two general classes: (1) Saws with teeth whose action is similar to that of a milling cutter. (2) Friction and abrasive disks.

METAL CUTTING SAWS are made in three varieties: (1) Teeth cut in the periphery of the disk. (2) Teeth inserted individually into the periphery of the disk. (3) Teeth cut in a segment of steel fastened to the periphery of the disk. Saws of diameters up to and including 8 in. generally are termed *metal slitting saws*. Saws of diameters 9 to 72 in. or more are generally referred to as *cold saws*, as they cut metal in the cold condition.

METAL SLITTING SAWS are made with a variety of tooth forms for sawing different materials. These saws are generally obtainable with side clearance and teeth having positive rake angles of 0 to 20 degrees. Saws without side clearance are used for slotting in order to hold a definite width of cut. Slitting saws with side milling teeth are used for heavier work and generally are made with alternate teeth having side clearance on opposite sides. For cutting cast iron, teeth are more widely spaced than for cutting steel, and rake angles of 3 to 5 degrees are commonly used. Nonferrous materials use widely spaced teeth and rake angles of 10 to 15 degrees, whereas steels utilize rake angles of 10 to 20 degrees with 5 to 10 degrees in the harder types. Saws with side clearance should be used wherever possible to reduce the side drag. Generally, the side clearance in slitting saws is machined into the disk either to the hole or to a hub of the same thickness as the new saw. Slitting saws are usually made of high-speed steel for production use.

Speeds and feeds using high-speed steel vary with the class of the material to be cut: Cast iron—speed of 60 to 90 ft per min, feed of 3 to 6 in. per min. Mild steel—speed of 100 to 125 ft per min, feed of 5 to 8 in. per min. Alloy steel—speed of 40 to 60 ft per min, feed of $^1/_2$ to 3 in. per min. Brass—speed of 150 to 250 ft per min, feed of 8 to 12 in. per min. Copper—150 to 350 ft per min, feed of 10 to 20 in. per min. Aluminum—speed of 500 to 1000 ft per min, feed of 10 to 20 in. per min. In general, higher speeds and feeds are used for the softer varieties of materials in each class.

INSERTED TOOTH SAWS were developed to allow a superior material to be used in the cutting action of larger saws and a lower quality steel to act as the disk and driving means. Inserted tooth saws are restricted to wider spacing of teeth because of strength requirements in transmitting the power from the disk to the tooth. The tooth is usually of a high-speed steel machined to fit into a socket provided in the periphery of the disk. The inserted tooth is machined with side clearance and is wider than the disk. Inserted tooth saws are used in metal cutting where wide tooth spacings can be used, depending on the type of material and the length of cut. Carbide-tipped inserted tooth saws are used in the cutting of nonferrous materials.

SEGMENTAL SAWS were developed to replace inserted tooth saws where heavy strains were to be absorbed by the saw due to cutting, without destroying the tooth mounting. The segments are generally of high-speed steel and are machined with side clearance and fastened by a suitable means to the thinner disk. The teeth are cut into the periphery of the segment. The segmental form allows a number of teeth to be cut on the segment with the result of narrower tooth spacing. These saws are adaptable to cutting all sizes of materials either ferrous or nonferrous.

SOLID CIRCULAR SAWS have teeth cut into the periphery and are generally made of semihigh-speed or high-speed steels with the side clearance cut into the sides of the disk to a hub. These are limited in use to smaller-diameter saws, usually under 24 in. for semihigh-speed and under 16 in. for high-speed steels.

Sharpening of metal cutting saws is generally done on either automatic grinders or hand-operated grinders. Various tooth forms are used to distribute the cutting load between successive teeth by breaking up the chip width. Most popular of the tooth grinds are the alternately high and low teeth in which the high tooth is beveled on both sides, leaving a cutting edge of one-third to one-half the width of the tooth in the center. The high tooth is often referred to as the roughing tooth, and the low tooth as the finishing tooth. The high tooth removes part of the chip width and leads the low tooth usually about 0.015 in., while the low tooth removes the remaining corners of the chip width and finishes the cut.

For longer saw life and faster cutting it is recommended that coolants be used wherever possible. Richer mixtures are generally used in circular sawing than in other types of machining, with mixtures running as high as 4 to 1 in soluble oils. For best results, as in all types of sawing, circular saws must be ground correctly. For mild steel cutting, a rake angle of 15 to 20 degrees is recommended, with a top clearance angle of 9 to 14 degrees. The top clearance angle should always be greater than the feed dictates lest the back of the tooth bind on the material being cut. Table 4 illustrates the rake angles, cutting speeds and feeds generally used in circular-sawing various metals.

Table 4. Cutting Speeds, Feeds, and Rake Angles for Circular Saws Having High Speed Steel Teeth

Material	Cutting Speed, ft per min	Saw Feed, in. per min	Tooth Rake, degrees
Aluminum—soft	2000–4000	25–40	20–30
Aluminum—hard	500–1500	15–30	10–20
Brass—soft	400–600	15–30	15–20
Brass—hard	300–450	8–15	10–15
Bronze	250–400	8–30	15–20
Cast iron	35–60	3–9	5–10
Copper	800–2000	20–40	20–25
Steels—40–65,000 psi tensile	80–100	5–8	15–20
Steels—70–85,000 psi tensile	60–80	5–8	15–20
Steels—85–100,000 psi tensile	50–65	4–7	10–15
Steels—rails—soft	55–65	3–6	5–10
Steels—rails—hard	40–55	1–3	5–10
Steels—cast—hard	40–55	3–6	5–10
Steels—tubes—thick wall	80–100	5–8	15–20
Steels—tubes—thin wall	120–160	6–15	15–20

FRICTION DISKS are relatively thin disks of alloy steel which are rotated at peripheral speeds of 20,000 to 25,000 ft per min. Although the trade often refers to the method as friction sawing, actually the cut is made by heating the work by friction of the disk to the molten or plastic state, and then removing it by notches or grooves in the disk. Generally there are two types of applications, cutting work in the hot condition and in the cold condition, which the trade calls "Hot Saws" and "Cold Saws," respectively. The *hot* disks are usually notched with V-type teeth, and the points swaged for side clearance. The *cold* disks are notched at regular intervals, usually by a chisel, to provide side clearance and roughen the friction surface. A flash of metal is generally left by the cutting action on the side where the disk leaves the work. Friction disks find application in mills and other places where quality of cut is not important. Friction disks are mounted on motor-driven machines and are usually water cooled. Rapid cutting times are obtained by this method, e.g., 8 to 12 in. I beams in 5 to 15 sec and 40 in. I Beams in 1 1/2 min.

ABRASIVE CUT-OFF DISKS are very thin abrasive wheels used in cut-off machines mainly for cutting smaller sections and bars. The method is applicable to cutting mild and hard materials of ferrous and nonferrous types generally using a coolant. The cutting speed of the disk is usually in the range of 10,000 to 16,000 ft per min.

CIRCULAR-SAWING MACHINES are built for cutting ferrous or nonferrous stock. Standard capacities will cut a range of sizes up to 14 in. by 24 in. or 16 1/2 in. diameter with one pass of the saw. Usually the work is cut singly, but in certain instances multiple setups are advantageous. In the sawing operation the work is clamped solidly and the saw fed through. Clamping and feeding are accomplished either mechanically or hydraulically. General-purpose sawing machines require manual loading of stock and operation of clamp and feed controls. Automatically operated circular-sawing machines are used where production quantities must be cut to a given length. Length tolerances of less than plus or minus 0.010 in. are obtained in sawing smaller size stock. Circular sawing features fast cutting with little or no burr left on the piece cut.

Circular-sawing machines are built with a range of feeds and speeds depending on the type of material to be cut. Saw speeds and feeds of ferrous and nonferrous metals generally fall within the range given in Table 4. The saw is usually driven by the spindle on which it is mounted. Power is transmitted to the saw spindle through a gear train from a motor drive integrally mounted on the machine. Another method of driving the saw employs a bevel drive gear which meshes with slots cut in the saw disk.

Several manufacturers utilize an *up-cutting* method on sawing machines designed for heavier work. The saw rotation in this method is such that the cutting load holds the front of the saw head against the ways. Chip-removers are used wherever possible in conjunction with the saw to remove unexpelled chips from the saw teeth. Such chip-removers generally mesh with the saw teeth, and are recommended particularly where ferrous alloys are being cut. A large variety of sawing machines has been built for such special production operations as cutting off sprues, gates, and risers on both large and small castings; for mitering large and small work; for cutting plates; and for performing machining operations.

GEAR-CUTTING PROCESSES

37. SPUR, HELICAL, AND WORM GEARS

Machining of gear teeth is performed in a variety of ways, all of which are based on planing, milling, or shaping. The processes generally are classified as (1) forming (milling), (2) template (planing), and (3) generating. It is not considered good practice to operate gears cut by the generating processes with gears cut by any of the others, and vice versa. Hobbed gears can be interchanged with shaper-generated gears provided proper tooling is used.

FORMING PROCESSES utilize a tool having the shape of the space between the teeth. The cutter may be a planer or shaper-type tool, which is reciprocated while being fed into the blank. One tooth space is cut at a time, after which the blank is indexed through an angle corresponding to the circular pitch of the gear. The method is slow, and for this reason is little used.

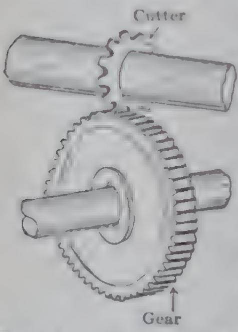

FIG. 1. Circular form cutter milling the spaces between the teeth of a spur gear. (Courtesy of Brown and Sharpe Manufacturing Co.)

Circular form cutters are milling cutters having profiles corresponding to the shape of the space between the teeth of the gear (Fig. 1). They find their widest application in job shops and for short production runs. Standard cutters are available for cutting teeth with a composite profile based on the 14 1/2-degree full-depth tooth with cycloidal modifications (see Article 3, Section 14). Theoretically, a different cutter is needed for each pitch and each gear diameter, inasmuch as the shape of the space is a function of base circle diameter as well as pitch and pressure angle. In practice a selection of 8 cutters is usually considered sufficient to cover the range from 12-tooth gears up to a rack. These are indicated by the whole numbers in Table 1. For greater accuracy in between these steps, additional cutters may be used. These, with their ranges, also are shown in Table 1. Special cutters may be obtained for specific numbers of teeth, as well as for special tooth forms.

Table 1. Cutters for Standard 14 1/2-degree Composite Gear Tooth Systems

Cutter No.	Range of Numbers of Teeth Cut Using Set of 8	Range of Numbers of Teeth Cut Using Set of 15
1	135–rack	135–rack
1 1/2		80–134
2	55–134	55–79
2 1/2		42–54
3	35–54	35–41
3 1/2		30–34
4	26–34	26–29
4 1/2		23–25
5	21–25	21–22
5 1/2		19–20
6	17–20	17–18
6 1/2		15–16
7	14–16	14
7 1/2		13
8	12–13	12

Helical teeth may be cut by circular-form cutters with the aid of a dividing head which imparts rotation to the blank corresponding to the lead of the helix. Selection of the cutter is based on normal pitch, number of teeth, and helix angle. Inasmuch as a section through the blank parallel to the plane of rotation of the cutter shows the pitch and base circles to be ellipses, the shape of the tooth space corresponds to a gear of radius equal to the radius of curvature of the ellipse at the end of the minor axis. An additional correction is required to avoid undercutting the flanks and relieving the faces of the tooth profiles, resulting in the following formula for formative number of teeth, N_f, to be used in selecting the cutter from Table 1:

$$N_f = \frac{N}{\cos^3 \phi} + p_n d \tan^2 \phi$$

where N = actual number of teeth in gear; ϕ = helix angle; p_n = diametral pitch of cutter = normal diametral pitch of gear; and d = pitch diameter of the cutter.

End milling cutters having profiles ground to the shape of the space between the teeth offer an alternative forming method (Fig. 2).

Broaching is used to cut the teeth of internal and external (Fig. 3) gears where the quantity justifies the cost of the tool. (See Article 33 in this section.)

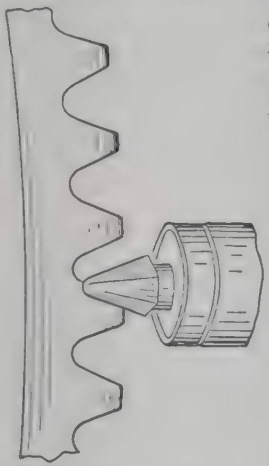

FIG. 2. Forming the space between teeth of a large spur gear by means of an end-milling cutter. (Courtesy of United Engineering and Foundry Co.)

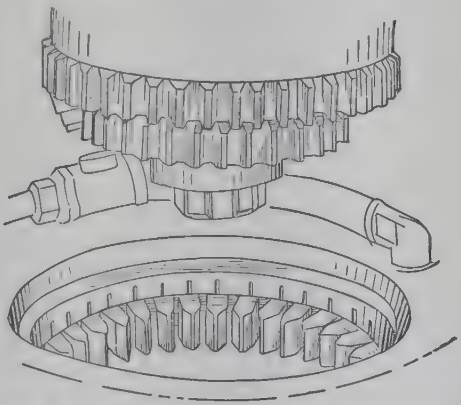

FIG. 3. Combination broaching and shaving a spur gear. (Courtesy of Michigan Tool Co.)

TEMPLATE PROCESSES employ a planing tool which is guided by a tracer mechanism, the tracer point moving over a template having the shape of the tooth profile. The method is used to make gears from forged blanks in which holes are first drilled in the area of the tooth space, the remainder of the metal being removed by the planer which produces the correct profile. It is also used for finishing teeth which already have been cast to shape approximately, and for cutting bevel gears. (See Article 38 of this section.)

GENERATING PROCESSES. Except for the broaching of internal gears, generation of gear tooth profiles represents the only method adapted to high production. Spur, helical, and worm gear generating processes may be classified as shaper generating and hobbing.

Gear shapers employ a cutting tool in the form of a rack or a pinion having the same pitch as the gear to be cut. In cutting a spur gear, the cutter and the blank are mounted on parallel axes and the cutter reciprocated axially while being fed into the blank until the pitch circles of cutter and blank are tangent (Fig. 4). Cutting of the gear is completed by rotating the cutter and the gear as if they were two gears in mesh, while the cutter continues to reciprocate. Helical and herringbone gears can be cut with equal facility by imparting proper oscillation to the work. Pinion-shaped cutters are adapted to all types of gears, including internal gears. Inasmuch as the involute rack is straight sided, a rack-type tool may be produced easily to consider-

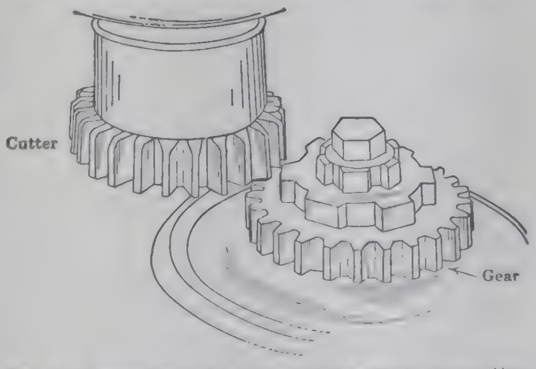

FIG. 4. Generation of a spur gear with a shaper type cutter. (Courtesy of Fellows Gear Shaper Co.)

able accuracy. The gear shaper-generating machine is not limited in scope to the production of gears but is adaptable to the making of a considerable variety of shaped parts.

Hobbing employs a rotating cutter known as a hob, which is, in effect, a worm gear having gashed teeth so relieved as to form cutting edges. The hob and blank are mounted on axes so oriented that the pitch helix of the hob is tangent to the pitch elements of the gear teeth (Fig. 5). For a helical gear, the angle between the axis of the hob and the plane of rotation of the gear, if both are right-handed or left-handed, is equal to $(\phi - \lambda)$, where ϕ is the helix angle of the gear and λ is the lead angle of the hob. If gear and hob are opposite handed, the angle would be $(\phi + \lambda)$. The speed ratio of the hob to the gear must be

$$\frac{\omega_h}{\omega_g} = \frac{N_g}{N_h\left(1 \pm \dfrac{f \tan \phi}{\pi D_g}\right)}$$

where ω_h and ω_g denote speed of hob and gear, respectively; N_g = number of teeth in gear; N_h = number of threads in hob; ϕ = helix angle of gear; D_g = pitch diameter of gear; and f = feed of the hob parallel to the axis of the blank for N_g/N_h revolutions of the hob. The plus sign is used when hob and gear are of the same hand, the minus sign being used where they are to opposite hand. While hob and blank are rotated the hob is fed parallel to the axis of the blank, thus generating all the teeth in one complete pass.

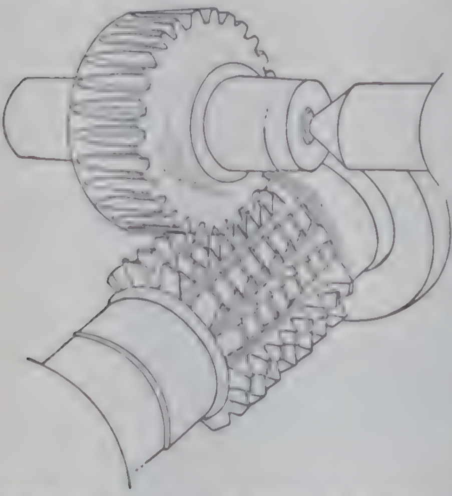

Fig. 5. Gear hobbing. (Courtesy of Michigan Tool Co.)

Hobs may be straight, for cutting spur and helical gears up to 35-degree helix angle, tapered for higher helix angles. Formed hobs are made for special work. One straight hob of given pitch can be used to cut any size of spur or helical gear of either hand up to 30-degree helix angle; above this angle the hob should be of the same hand as the gear. For greatest accuracy ground single-thread hobs are recommended, but multiple-thread hobs give higher production.

GEAR FINISHING. Shaving, burnishing, lapping, or grinding, or a combination of these improve surface finish and accuracy over and above that possible by the foregoing methods. In particular, distortion during heat treatment necessitates subsequent refinishing.

Shaving involves the use of a cutting tool in the form of a hardened helical pinion or rack with teeth serrated at points along the face. The cutter and gear are run together in mesh at high speed (Fig. 6), the cutting action being obtained either by running on crossed axes (5 to 10 degrees usually) or by reciprocating the shaving tool at comparatively high speed. Where shaving is used as the finishing process, the rough cutting is usually done with a special tooth form which produces an undercut, thus eliminating the possibility of gouging the root fillet, and confining the finishing operation to the tooth faces.

Burnishing consists of running the gear in mesh with three hardened burnishing gears finished slightly oversize, pressure being applied to the burnishing gears. Mating gears, particularly if hardened, can be burnished by running in mesh with each other.

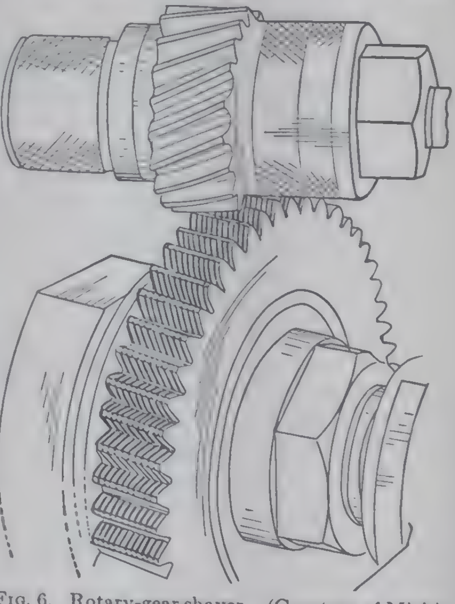

Fig. 6. Rotary-gear shaver. (Courtesy of Michigan Tool Co.)

Grinding machines for gears employ either the forming process or the generating principle.

In form grinding the abrasive wheel has the shape of the space between the teeth and is used in a similar manner to form cutters. The diamonds which true the wheel are controlled by a suitable mechanism based on the use of templates.

Generating gear grinders employ a narrow straight-sided abrasive wheel, the flat side of which corresponds to the profile of an imaginary rack tooth. The machine imparts relative motion to the gear and the wheel similar to that of the gear meshing with a rack.

When gears are to be finished by grinding, special roughing cutters are generally employed in the preliminary stages of manufacture. These cutters are designed to provide a variable allowance for stock removal along the tooth profiles, tapering from a maximum at the tips to zero in the region of the fillet.

Lapping usually is done by rotating the production gear in mesh with a lapping gear in the presence of an abrasive compound. The gear and lap are so mounted that an endwise sliding motion occurs between the teeth. Sometimes production gears are lapped with each other.

Laps are sometimes made with high or low pressure angles with respect to the piece to be lapped, so as to remove metal in specific contact zones.

38. BEVEL-GEAR CUTTING

By Allan H. Candee

The tooth profiles of bevel gears are generated by tools carried on a rotating cradle and representing teeth of a crown gear or another bevel gear. Machines differ principally in the type of tool used. Straight teeth are cut by tools reciprocating on straight slides, and curved (spiral) teeth usually by rotating cutters.

STRAIGHT BEVEL GEARS. Method 1. Generation. Two reciprocating tools represent teeth of an imaginary generating crown gear, and work on opposite sides of the tooth being generated. After one tooth is finished the blank is indexed for the next tooth. Tools with straight cutting edges generate curved tooth profiles as the result of relative motion, obtained in some machines directly by rolling segments and in other machines by gear trains. (See Figs. 7 and 8.) This is the method most widely used. Machines of latest type generate slight lengthwise crowning so as to ease off the contact at the ends of the teeth. Straight bevel-gear generators range in capacity up to approximately 30-in. gear diameter or 15-in. cone distance.

FIG. 7. Principle of bevel-gear generator.

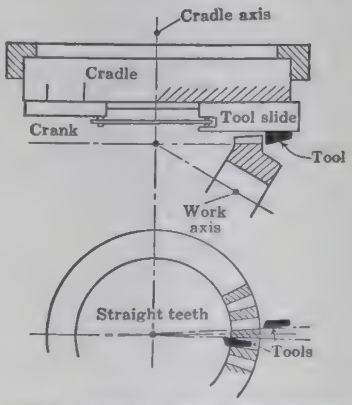

FIG. 8. Straight bevel-gear generator.

Method 2. Generating-milling. For mass production of gears for automobile differentials and similar applications, the so-called Revacycle process was introduced in 1938. A continuously rotating disk cutter feeding from end to end of the teeth rough-cuts and finishes a tooth space during each revolution. The teeth of the cutter vary in height, thickness, and form in order to produce properly tapering bevel gear teeth. The method is three to four times faster than any other. A special cutter must be calculated and manufactured for each job, which makes the process uneconomical for small quantities.

Method 3. Form-planing. In bevel-gear planers a single reciprocating tool with rounded point is controlled by a former to produce the profile shape of the tooth. Different formers are required for different-pitch angles. This is the oldest type of correct bevel-gear-cutting. Gear planers have been built to cut gears up to 20 ft in diameter. Planer-cut gears are not equal to generated gears in smoothness of action.

SPIRAL BEVEL GEARS. Method 1. (See Fig. 9.) Rotating cutters of face-mill type are used for most spiral bevel gears up to about 30-in. diameter. A relative motion between the work spindle and the cradle generates conjugate tooth profiles. Most "flat" gears for tooth ratios of 3 to 1 or higher are cut without generation and are known as Formate gears. All other gears and pinions are generated. Machines can be set to cut any spiral angle from 0 degrees up.

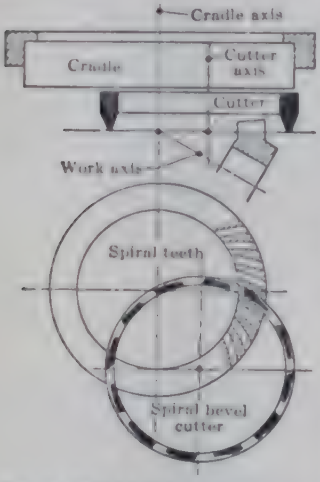

Fig. 9. Spiral bevel-gear generator.

Method 2. Larger gears, up to about 100 in. in diameter or 50 in. cone distance, are cut on planing generators by single reciprocating tools with side-cutting edges and with continuous rotation of the blank.

Method 3. In Germany a method of generating spiral bevel gears by means of taper (conical) hobs is used to some extent. Although invented in the United States, this method has not been adopted here.

HYPOID GEARS are so closely related to bevel gears that the same machines are used for both. It is necessary, however, that the workhead be provided with vertical adjustment. For generating a hypoid pinion the work spindle must be offset *below center* or *above center*.

TOOTH GRINDING. Spiral teeth of the type produced by the rotating spiral-bevel cutter can be ground after hardening. A grinding wheel in the general form of the cutter is used. The gears may be bevel or hypoid, and the teeth may be generated or Formate. Gear sizes are limited by machine capacities.

SUPPLEMENTARY MACHINES. Roughing machines are customarily used for gears of large and intermediate pitches. Burnishing and lapping machines are used in production shops.

TESTING MACHINES. On these machines the gears are set in correct position and run together under a brake load. Smoothness of action, sound, and tooth bearing can all be observed. Testing in this way is essential for demonstrating the correctness of bevel gears in the finished state and during manufacture.

DESIGN AND MANUFACTURE. Various combinations of cutters and machine settings may be used to cut a gear and pinion of given numbers of teeth and pitch. Spiral-bevel teeth may be generated, either one side at a time or both sides in one operation. The method to be used often depends on cutters and machines available in a given shop. Exact details of tooth design therefore should be determined after consultation with the gear manufacturer.

FLAME CUTTING

By C. W. Obert

39. GAS CUTTING

Gas cutting of ferrous metals is a process of preheating material to its kindling or ignition temperature and then oxidizing it rapidly by means of a closely regulated jet or stream of oxygen issuing from a special *cutting blowpipe* or *torch*. Hence the process is primarily chemical, based on the chemical affinity of oxygen for ferrous metals that have been heated to the kindling temperature or higher.

The chemical reaction that results when commercially pure oxygen is brought into contact with most steels or iron at the kindling point is very active. For this carbon steel must be preheated to a bright red color, a condition reached between approximately 1400 and 1600 F. For accurate control, both the gases supplied and the rate of progression of the cutting should be closely regulated.

Only the metal within the direct path of the oxygen jet is acted upon. In linear cutting, a *kerf* is formed having uniformly smooth and parallel walls. Under skilled workmanship, using mechanically guided cutting torches or blowpipes, cutting tolerances, with respect to squareness and longitudinal alignment of the cut surface, may be held very closely.

The faces or walls of the kerf, in the commonly used carbon steels, are not injured by the cutting operation. On the contrary, the strength and toughness of the faces are slightly increased. The effect of heat on the metal, as a result of normal cutting operations, rarely penetrates farther than approximately 0.1 in. below the cut surface, except in the so-called stainless steels, where precipitation of carbide may extend as far as 0.375 in.

In addition to linear gas cutting or severing, other types of controlled oxidation are in use, employing the free-burning reaction of oxygen with ferrous metals that have been heated to kindling temperature, in order to sever, shape, and work such materials. One application, known generally as *oxygen-lance cutting*, utilizes a relatively long section of small-diameter iron pipe. A pipe with a stream of oxygen flowing through it is ignited and kept aflame, thus forming a lancelike cutting tool that furnishes preheat as well as free oxygen for cutting and is used primarily for emergency and heavy-duty cutting, such as opening furnace tap holes.

Another application of gas cutting is known as *flame machining*. This method is used primarily to surface ferrous metals in much the same way as a planer or milling machine. The cut does not penetrate the work as in severing or linear gas cutting.

In actual gas cutting, the iron or steel removed from the kerf is, as already noted, not entirely oxidized or consumed by the oxygen. Because of the eroding effect of the cutting oxygen jet, however, about 30 to 40% of the metal is washed out of the cut as unconsumed or metallic iron. As a result of this fortunate circumstance, it is not uncommon to obtain satisfactory cuts with a consumption of cutting oxygen less than one cubic foot of oxygen per cubic inch of material removed from the kerf.

FUEL GASES. A number of fuel gases of high flame temperature have been employed for cutting ferrous metals, with varying degrees of success. The more important of these are acetylene, hydrogen, city gas, natural gases, coke-oven gas, ethylene, and the lighter petroleum distillates, including methane, ethane, propane, and butane.

Aside from hydrogen, all these fuel gases are hydrocarbons and give off carbon dioxide (CO_2) and water vapor (H_2O) as products of complete combustion. They may be burned in different manners but, when used for gas cutting, the combustion is made to take place in the way that will develop maximum flame temperatures. For quick starting and rapid progress of a cut, hot preheating flames are a prime essential. This requirement is fulfilled by designing cutting torches or blowpipes that burn the fuel gases according to the Bunsen principle and premix commercially pure oxygen instead of air with the gases before combustion. The substitution of oxygen for air, in the primary combustion, results in a notable increase of flame temperature of the fuel gas, because the nitrogen, constituting nearly four-fifths of the air, does not need to be heated by the flame when oxygen is used. Acetylene produces a hot, short flame, with an easily distinguished, bright inner cone; the hottest point is at the tip of the inner cone.

FLAME CHARACTERISTICS. Depending on the ratio of oxygen to fuel gas in the mixture, the characteristic of the flame produced may be carburizing, neutral, or oxidizing. The neutral flame results when just sufficient oxygen is supplied to complete the primary combustion in the inner cone of flame, yielding carbon monoxide (CO) and hydrogen (H_2) as products. Neither of these two gases carburizes or oxidizes molten metal; in fact, both are neutral to it. Regardless of the amount of primary oxygen supplied, complete combustion in the inner cone of flame is impossible since, at such extremely high temperatures, carbon dioxide and water vapor are unstable and dissociate or revert in part to carbon monoxide, hydrogen, and oxygen. This dissociation limits maximum temperatures attainable in a flame of oxy-fuel gas; otherwise these temperatures might go much higher.

Maximum flame temperatures are obtained with a neutral flame. With strongly oxidizing flames, however, burning of the metal itself occurs, and this type is generally used for gas cutting. Oxidizing flames preserve the general appearance of neutral flames, but their inner cone is shorter, "necked in" on the sides, and more sharply defined. Because of dissociation, the products of the primary combustion in the inner cone of excess oxygen flames consist of carbon monoxide, carbon dioxide, hydrogen, water vapor, and free oxygen, in proportions that depend on the amount of excess oxygen premixed with the fuel gas.

Secondary combustion of the fuel gas takes place in the outer or envelope flame. Here any carbon monoxide and hydrogen contained in the primary combustion products complete their combustion to carbon dioxide and water vapor, respectively, since the lower temperature is insufficient to cause dissociation of these latter compounds. The necessary oxygen required for completing the secondary combustion in the envelope flame is taken from the surrounding air by diffusion into the zone.

Most hydrocarbons are exothermic, generating heat during formation and absorbing the same amount of heat during combustion. But acetylene is highly endothermic, absorbing heat during formation and liberating it during burning or decomposing. The endothermic heat liberated by acetylene is in addition to that produced by the combustion of its component elements.

Acetylene contains the highest percentage of carbon (92.3% by weight) of any common gaseous hydrocarbon compound. This, coupled with its exceptionally large endothermic heat, gives it the highest flame temperature of any known fuel gas, by a wide margin.

EFFECT ON METAL STRUCTURE. In gas cutting, the temperature of a slight depth of metal immediately adjacent to the cut face is raised considerably above the transformation range. As the cut progresses, the steel cools again through this range. The speed of cooling depends on the heat conductivity of the surrounding metal, radiation losses, and the fact that the heat is applied only momentarily at any given point, since the cutting torch is kept in constant motion while cutting. When the steel being cut is at room temperature, the rapidity of the cooling is sufficient to have an actual chilling or quenching effect on the cut edges, particularly in heavier cuts involving large masses of cold metal.

When etched specimens are examined under the microscope, the material is found to be altered when compared with the original metal. However, the change is largely a physical one, concerned with crystalline grain structure. The normal pearlitic steel is transformed into one or more of several structures ranging from spheroidized carbides in ferrite to the harder constituents, depending on the particular chemical composition of the steel cut and the rate of cooling after the cutting operation, as well as the carbon content and the alloying elements present. Also the heat developed by the cutting makes the grains at the edge of the cut either larger or smaller than the unaffected grains behind the cut edge.

LOW-CARBON AND MILD-CARBON STEELS. At normal temperatures, gas cutting of carbon steels that contain less than 0.30 or 0.35% carbon is not detrimental unless alloying elements are present. Gas-cut edges of such steels are suitable for any uses where edges are employed that are prepared by any of the mechanical methods of severing, such as planing, milling, shearing, friction sawing, and grinding. Gas-cut edges are adapted to applications involving stresses, such as mechanical calking and holes in which tubes are to be expanded or rivets driven. Clean, smooth gas-cut edges of low-carbon or medium-carbon steel plates or forgings have physical properties that render them actually superior to edges that are sheared, planed, or otherwise prepared mechanically.

Where edges are gas beveled to form a V for welding, and later are welded together by either oxyacetylene blowpipe or electric arc, the heat of the welding operation acts to dissolve all marginal structures previously formed and operates to anneal the metal for an appreciable depth below the cut surface. Any change in structure that the preceding cutting may have produced in and adjacent to the cut surface is therefore obliterated.

Tests of flame-cut edges of low-carbon and medium-carbon steels to determine their physical properties (such as hardness, ductility, microstructure, and resistance to impact) have shown that they are satisfactory for almost any type of mechanical treatment or character of service.

HIGHER-CARBON AND ALLOY STEELS. Gas cutting of higher-carbon and alloy steels, particularly at room temperature, may produce a thin layer of hard material on the cut surfaces, which may not be sufficiently ductile to withstand the stresses set up in cooling, without cracking, or the stresses imposed by the subsequent use of the part cut. The torch heats the steel at the cut edges to a high temperature momentarily, but normal thermal expansion is prevented by the adjoining cold metal. The action called *upsetting* results. Later, when cooling occurs, contraction of the upset metal may develop severe stresses in tension along the cut edges. With these steels, the ductility may not be sufficient to prevent incipient cracks and checks that can prove dangerous in service, since they are likely to develop into large fractures.

Experience has shown that if these higher-carbon and alloy steels are preheated and, in certain instances, annealed afterward, no cracks will occur on the cut edges. Naturally, with the adjoining metal preheated, the difference in expansion is less between it and the metal heated during cutting, and upsetting is greatly reduced or eliminated.

When equipment is used that delivers large volumes of oxygen through large tips at low pressures, large billets and rounds are successfully cut at rolling temperatures (1700 to 1800 F). Occasionally very high cutting speeds are obtained. Evidently, at temperatures above the transformation range, steel reacts more vigorously with the cutting oxygen, producing slags with great amounts of iron and relatively little Fe_3O_4.

To obtain the most efficient use of the oxygen and, at the same time, leave the steel in the best condition, a preheat temperature of 500 to 600 F should ordinarily suffice for carbon steels. The additional expense that accompanies preheating is compensated for by the more rapid rate at which preheated steel can be cut.

Annealing completely restores the original pearlitic structure of the steel at the cut edges, wherever this may be desired, and removes any residual stresses set up in the metal. The majority of steels do not require annealing if they have been preheated before the flame cutting.

GAS-CUTTING EQUIPMENT consists ordinarily of the cutting torch or blowpipe with separate cutting tips of different sizes, oxygen and fuel-gas hose with connections, oxygen and fuel-gas pressure regulators, and gas cylinders. The pressure regulators are usually equipped with cylinder and working-pressure gages. Regulators for the cutting oxygen are designed especially to deliver oxygen in large volumes and at higher pressures and, hence, are usually fitted with gages that measure working pressures as high as 400 psi.

Where large quantities of oxygen are required, oxygen cylinders are often manifolded. Acetylene generators, rather than cylinders, are used where the consumption justifies it. In such installations, distribution pipe lines are frequently employed to carry both gases to the various points of consumption throughout the premises. For gas cutting by machine, the torch is held and operated mechanically, but its essential features and the accessory equipment remain unchanged. To insure safety and efficient results, the manufacturer's instructions for setting up and operating the equipment should be followed closely.

DRAG. In flame cutting, the jet of cutting oxygen usually enters the cut in line with the axis of the cutting oxygen orifice. After traversing about one-half the thickness of the cut, however, the jet may curve backward in a direction opposite to the travel. When this occurs, the amount by which the oxygen jet falls behind the perpendicular in passing through the material is known as the "drag" of the cut. Faint markings or ridges called "drag lines," left on the face of the cut, enable the drag to be measured. In heavy cuts, these drag lines are more pronounced. Cuts with short or negligible drags are known as *high-quality* cuts; those with long drags are termed *low-quality* cuts.

Cutting studies have shown these facts: (1) As the drag is decreased, the oxygen consumption is increased. For very short drags, a slight decrease in drag length can be procured at the expense of increased oxygen consumption. (2) Except for low cutting speeds, a certain minimum length of drag is characteristic of a given tip and speed regardless of the operating pressure (or the oxygen consumption). (3) An increased drag may result if an attempt is made to obtain a drag shorter than the minimum by increasing the operating pressure beyond that at which the minimum drag is obtained.

In considering the costs of flame cutting, therefore, it is essential to determine how short the drag must be to fulfill the requirements. If it is too long, a final corner will remain uncut, and this is usually not permissible. Straight-line cuts can frequently be made with considerable drag, without a particularly detrimental effect, since the drag lines lie within the plane of the cut and do not prevent both top and bottom edges of the cut from being left clean and sharp. This procedure, which saves considerable oxygen, is also applied in cutting scrap, where cut quality is nonessential as long as severing is accomplished. However, in cutting shapes, when rounding curves or corners, less drag is permissible, because the bottom contour of the cut will tend to come out different from the top, with the edges not square. Such cuts must be made with short drag. They require a good deal more oxygen than long-drag cuts that barely penetrate the material. Precision-machine flame cuts are necessarily of high quality.

PRESSURE. In heavy cutting, greatest care must be used in selecting the proper operating pressure. Not only is the range of suitable pressures considerably narrower for the heavier cuts, but the pressure also decreases at the hose-line connections, and a larger torch should be used with the increasingly greater flows of oxygen required for heavy cutting. The large volumes of oxygen needed are better supplied through the use of lower pressures and torches with large cutting orifices. Extreme preheating is necessary. Attempts to obtain the quantity of oxygen required by the use of high pressures in common machine cutting torches result in gouges and pockets in the kerf. Variations in the quality of steel are more important in heavy cutting.

Considerable skill is sometimes required for starting a heavy cut, in order to sever the initial lower corner completely and to avoid pocketing the stream of cutting oxygen in the lower portion of the cut. It is essential that the front edge of the cut be very clean, particularly the lower portion of the front face. To align the axis of the tip with the front edge of the material, the stream of cutting oxygen should be turned on with preheating flames burning to render it visible. In starting the cut, the movement of the torch should be retarded just long enough to allow the cutting stream to attack the material actively throughout almost the entire depth. Then the torch is permitted to proceed normally. If the piece is very heavy, the lower portion of the front face is sometimes heated with a large welding flame. In certain instances, starting is facilitated by first undercutting the forward edge of the material with a hand-cutting torch. However, unless the operator is experienced, the resulting cuts may be poor and ragged.

Care is required also in completing the final corner of heavy cuts. A slight retardation of the forward movement of the torch is desirable here as well.

THICKNESS. When the standard cutting torches are not assisted by oxygen lances, present limits of penetration are about 36 in. for manual cuts and 54 in. for machine cuts. Particularly for freehand flame cutting, the upper limit depends largely on the skill and steadiness of the operator. With oxygen lances it is possible to penetrate virtually any thickness of metal.

MATERIALS. Almost any ferrous material can be cut by gas; however, certain steels contain sufficient alloying elements to offer considerable resistance to the process. The uncombined carbon in cast iron has a similar effect. For such materials, special flame-cutting techniques must be applied, as described later. Oxygen lances permit penetration of virtually any metal, ferrous or nonferrous.

CROSS-CUT TOLERANCES. Where the torch is held firmly and advanced at uniform speed, as in machine flame cutting, cross-cut tolerances can be kept within narrow limits. In ordinary steel 6 in. thick, cut surfaces can be held to cross-sectional squareness accurate within $\frac{1}{8}$ in. Cuts in thinner sections can be held to proportionately smaller limits. The degree of longitudinal precision of a machine cut depends on the trueness of the guide rails of the cutting machine, the clearance of the operating mechanism, and the regularity of the propelling unit. Machine cuts can be made so smooth and square and can have such sharp edges that they require no further finishing of any kind.

BEVELS. Angular or bevel flame cuts are accomplished by inclining the torch and tip sideways to the desired angle or by using a bent tip. Such cuts may be either by hand or by machine, in straight or irregular lines, and with the same range of depth as in normal cutting at right angles. The usual angular limits of bevel and straight-faced fillet cutting range from 10 to 60 degrees.

SHAPES. Straight lines, circles, or contours of the utmost complexity are flame-cut with equal ease by either mechanical or hand-guided torches. Flame cutting, in sharp contrast with most machine-tool processes, has almost unlimited flexibility in this respect.

MULTIPLE-TORCH CUTTING. In many applications of machine flame cutting, as many as twenty torches are used to cut a like number of identical shapes simultaneously. Concentric circles for flanges and the like are often cut in one operation, with two or more torches.

When the sheets are thin and level enough to be clamped economically into a tight pile, stack cutting is indicated for multiple production. When the plate is heavy or wavy, multiple cutting is used—sometimes along with stack cutting.

STACK FLAME CUTTING. The operation known as *stack flame cutting* offers a means of cutting several thicknesses of metal simultaneously with a single torch, instead of employing multiple-torch cutting.

The plates in the stack should be clean and flat, with edges in alignment where the cut is started. The number varies with the thickness of individual plates, to keep the thickness of the stack within reasonable limits. The plates should be clamped together firmly, as nearly as possible along the line of cut. When thin plates are to be flame-cut in stacks, a *waster plate* that has sufficient rigidity to lie flat while the cut is being made is usually clamped on to prevent the top thin plate from buckling with the heat. A waster plate serves also to maintain ignition in the cut by its own combustion, thereby increasing the speed of cutting in this kind of work.

UNDERWATER CUTTING. Equipment for underwater cutting has been highly developed. Although oxyacetylene is used for shallow work, the pressure of acetylene needed soon rises to more than 15 psi because of the hydrostatic head. As a result oxy-hydrogen torches are used at depths greater than 25 ft. Operation under water involves the creation of an artificial atmosphere or *bubble*, in which the preheating flames burn and in which the actual cutting is done. Some torches create such a bubble by the use of a skirt around the tip. The skirt is filled with the combustion gases in order to keep the water away from the flame. The most successful equipment for deep-water operation requires a supply of compressed air to form the bubble in the skirt.

Operating pressures are determined largely by the hydrostatic head to be overcome. The chilling effect of the water on the work requires heavier preheats. Because of the difficulties under which the diver must work—such as clumsy dress, darkness, insecure footing, cold, and high pressure—only severing cuts are made, and oxygen and acetylene consumption figures are meaningless, although the specific cutting speed may be higher than in the open air.

Another form of underwater cutting equipment uses the electric arc for preheating.

40. ELECTRIC-ARC CUTTING

The process of electric-arc cutting consists in applying the heat energy of the electric arc to melt the metal along the desired line of cut. Because of the extremely high temperature developed in the electric arc, it can be used to fuse almost any material that conducts electricity, and in this way it is employed for cutting metals. Arc cutting is not a true burning process, since the metal is merely melted away. Arc cutting does not equal gas cutting in smoothness, quality, or accuracy of cut surfaces, and hence is not used where high-quality, accurate cuts are required. However, it is useful where smooth, uniform cut surfaces are not essential, and mere severing is the main object, as in scrapping operations. Arc cutting is used also for metals not easily cut in any other manner, such as cast iron, manganese steel, and large sections of nonferrous metals. It is applied particularly to the cutting of risers from large manganese steel castings. Arc cutting is also used for the cutting of rivets and piercing of holes.

CARBON-ARC CUTTING consists essentially of drawing an arc between a carbon or graphite electrode and the material to be cut. Direct current is generally used, with the carbon electrode negative (straight polarity), although alternating current can be used also. Graphite electrodes are preferred to carbon electrodes because they have a much longer service life and retain a point longer. A point is essential for clean, smooth cuts. The heavy currents used for arc cutting make ordinary electrode holders unsuitable except for light work. Special holders are recommended that have a long shank, a special mechanism for gripping, and a shield for protecting the hands.

MANIPULATION of the cutting arc, when cutting plates $^1/_2$ in. thick or less, consists simply in advancing along the line of cut at a rate equal to that at which the metal is being melted away. The most smooth and uniform cuts are made when the plate is in a horizontal plane, but the operation may be performed when the plate is in an inclined or a vertical position. For horizontal cutting, the electrode is held vertical or pointed slightly forward. For inclined or vertical cutting, the electrode is pointed downward. When materials heavier than $^1/_2$ in. are being cut, the vertical face of the cut is melted away progressively from top to bottom. Thus the bottom of the cut is advanced slightly ahead of the top of the cut, producing an undercut that permits the molten metal to run out more easily. Skilled operators can make narrower cuts. The width and speed of the cut increase with the current and the diameter of the electrode.

ARC CUTTING WITH COATED ELECTRODES. The application of heavily coated electrodes to cutting is not always an economical process, but it has certain merits, particularly where no oxyacetylene cutting torch or graphite electrode is available. Electrodes with either a gaseous or slagging type of coating can be used, but the slagging type gives better results because it will handle higher current densities. Plates $^3/_8$ in. thick or less can be cut simply by advancing the electrode along the line of cut. On heavier plates the electrode is pointed forward and moved from the top to the bottom of the cut, so as to keep the bottom slightly ahead. Electrodes smaller than $^5/_{32}$ in. in diameter are not suitable for arc cutting. The width of the cut is approximately constant for all electrodes $^1/_4$ in. in diameter or less. Alloy steels and many nonferrous metals can be cut readily by the coated-electrode cutting process.

OXYGEN-ARC CUTTING WITH HOLLOW ELECTRODES. Using the equipment and technique described for underwater cutting with an oxygen arc, rough cuts at high speeds can be made in air if the work piece is moderate in thickness. However, the electrode must be changed at frequent intervals, and the speed decreases when the sections to be cut are heavy.

SPECIFICATION OF DIMENSIONS AND TOLERANCES

By Harold S. Sizer

1. DIMENSIONING

There are two basic purposes to be accomplished in dimensioning a drawing: *First:* The dimensions must define the piece exactly, giving workmen and inspectors a positive understanding of the form desired by the designer. *Second:* The dimensions must recognize how the piece is to be manufactured and should give the workman producing the piece as much help as possible.

STANDARDS. Some good help in fulfilling these basic purposes is given by two standards:

(1) American Standards Association Z14.1-1946, *Drawing and Drafting Room Practice.*
(2) Society of Automotive Engineers, *Aeronautical Drafting Manual.*

Much of the material in the following paragraphs has been suggested by or taken from these standards. Do not, however, hesitate to deviate from these standards when such deviation will help a drawing to fulfill its basic purposes. Recognize, also, that drawings made in different plants for the same piece can be dissimilar in dimensioning and still comply rationally with the basic requirements, for methods of manufacturing have a strong influence on the specification of dimensions and tolerances.

USE INCHES. If your work falls in the class where lengths are mostly less than 100 in., use inch values exclusively. No unit need be given with the dimension values; and, wherever a figure appears without units specified, it is understood to be inches (Fig. 1).

FIG. 1. Dimension in inches.

FIG. 2. Dimension in feet and inches.

In structural work, long lengths are specified in feet and inches. Here a unit (′) is given to identify feet, but inches are understood (Fig. 2). A hyphen should separate the numerals for feet and inches.

HOW WILL PIECE BE MEASURED? Try to specify a dimension in the form in which it will be measured, for every time an operator has to transpose drawing figures to working figures there is a possibility of error.

If the lengths between shoulders on a shaft will be turned to scale measurements, dimension these lengths with fractional figures which can be read on the common sixty-fourth scale. No limits need be placed on fractional dimensions because their use indicates that the practical accuracy with which a sixty-fourth scale can be read (±0.010) is acceptable as the tolerance. Some companies extend the tolerance to $\pm ^1/_{64}$ (Fig. 3).

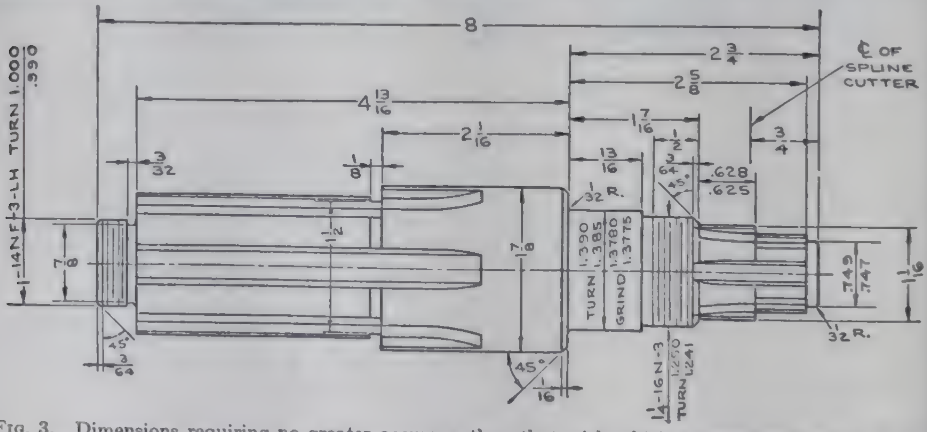

FIG. 3. Dimensions requiring no greater accuracy than that with which a sixty-fourth scale can be read are given in fractions. Where greater accuracy is needed, decimal limits are specified.

If the ground diameter of a sleeve will be checked with a micrometer, dimension it with decimal figures that can be read directly on a micrometer (Fig. 4).

If a ground and lapped roller (Fig. 5) will be checked for diameter and taper in a comparator, dimension it with plus and minus limits that may be read on the zero center scale of a comparator.

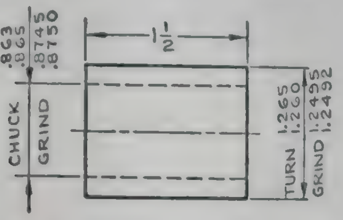

Fig. 4. Use of dimensions that can be read on a micrometer.

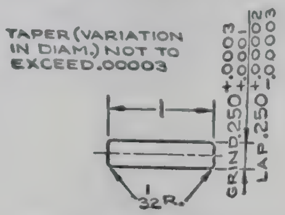

Fig. 5. Dimensions that may be read on a comparator.

If a screw thread is to be made to NF-3 gages, dimension it as an NF-3 thread and avoid the confusing details of pitch-line dimensions which are best checked by the gages.

If a first piece will not justify tools and must be laid out before machining, dimension the piece using arcs, radii, and angles so that a machinist with his square, center punch, and dividers can readily mark out and then machine the part.

POSITION OF LIMITS. As a workman reads a drawing, the upper or top figure on a dimension line is most likely to catch his eye. Make this figure the extra stock or first approached limit, which leaves him the tolerance to go if another or corrective cut is necessary. On an outside diameter this calls for the high limit on top whereas, for a hole, positions would be reversed (see Fig. 4). The width of a land would have the largest figure uppermost; for a slot the smallest figure would be given the top position (Fig. 6).

REFERENCE LINES. The reference-line method of dimensioning is a simple way to control the surfaces of a part. A few important surfaces, which will be established in the first machining operations, are taken as reference lines or planes, and all dimensions are given from these reference lines. Figure 7 is such a drawing. Each point, axis or surface, has an absolute position within the limits of its own tolerances and is not affected by the tolerances used in machining intermediate surfaces. Tolerances are not cumulative as they are in step-to-step dimensioning, and an operator does not have the responsibility of balancing plus and minus deviations incurred in successive operations.

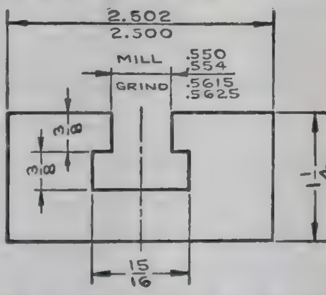

Fig. 6. Dimensioning so that top figure of limits corresponds to extra stock.

Reference-line drawings are particularly helpful in tool work or work to be done on jig borers. The work tables on these machines can be positioned with micrometer accuracy, and settings are readily made when drawings give dimensions from reference lines.

A shaft dimensioned from a reference line established at its largest shoulder is shown in Fig. 3. Note that there is one close relationship of shoulders which is dimensioned with a small tolerance and does not conform to the strict rules of reference-line dimensioning. To maintain the close tolerance length by reference-line dimensioning, it would be necessary to hold two shoulders to very close tolerances in order that the difference between them would be within the desired limits. It is a less costly operation to machine a single shoulder to get a desired length between shoulders than it is to machine two shoulders accurately to obtain the same between shoulder length. Departures from reference-line dimensions are approved where they will simplify shop work. Figure 8 shows a gear center distance dimensioned independently.

SCREW THREADS. Most screw threads are made to the American Standard, which is described in American Standards Association B1.1-1949, *Screw Threads*, or in Screw-thread Standards for Federal Services, *National Bureau of Standards Handbook* H28 (1944). See also Section 10, Article 2, of this volume.

In dimensioning, it is necessary only to give the OD of the screw and to identify the type, size, and class of the screw thread (see Fig. 9). It is assumed that the thread will be cut to, and inspected with, thread gages and that details of pitch diameter, included angle, etc., are not necessary on the drawing. All threads are right hand unless LH (left hand) appears on the drawing. If full threads must approach close to a shoulder or to the bottom of a hole, this should be specified with a dimension on the drawing.

Large machine screws and special screws should be specified in complete detail (Fig. 10). Operators doing the turning, milling, and grinding should find all necessary figures on the drawing and should not have to hunt up values for wire measurements or lead angle.

Fig. 7. Dimensioning from a reference line or surface.

HOLES. Holes to be drilled are dimensioned with a leader line and a note such as:

3/8 DRILL—6 HOLES

The total number of similar holes is specified to reduce congestion on the drawing. It is understood that the tolerance on a drilled hole is plus or minus 0.010. No limits are placed on the drawing (Fig. 8).

Counterbored holes are treated in the same manner as drilled holes. It is, however, often convenient to add the depth of counterbore to the leader note (Fig. 8).

Reamed, bored, or ground holes should be dimensioned with high and low limits.

POINTS FREQUENTLY OVERLOOKED. Do not expect a workman to do your arithmetic. Every time an operator has to recompute dimensions there is a chance for error.

Do not dimension from imaginary lines such as center lines or pitch lines; you cannot butt a scale against a center line or set the anvil of a micrometer on a pitch line.

Do not hide behind "good practice" and assume that tolerances are understood. If run-out should be less than 0.0005, put this on the drawing; and if taper should not exceed 0.00025, say so.

Do not specify a dimension in two ways and thus produce a conflict of tolerances. If you put tolerances on all the component lengths, do not put a tolerance on the total length. If you want a tolerance on overall length, leave off the tolerance on some one of the steps.

Fig. 9. Screw-thread identification.

Be sure that the surface from which you are dimensioning actually exists at the time the dimensioned operation is being performed.

Do not present a workman with an upside-down view of his work, especially if it contains unsymmetrically located holes. As he looks down on the work piece in the vise or on the machine table, he should see the same plan as that presented on the drawing.

PRACTICAL TOLERANCES. The accompanying table suggests the tolerances which can be maintained in various machine tool operations. See Art. 2 for definition of tolerance. There are a thousand exceptions to this table and the values given must be modified to suit the peculiarities of each part, the abilities of the operators in the plant, and the condition of its machine tools.

Suggestions on Specifying Tolerances

Operation	Diameter				Length				Face or Shoulder Runout			
	Size	*C*	*B*	*A*	Size	*C*	*B*	*A*	Size	*C*	*B*	*A*
Turning	Under 6 in. diam.	.005	.002	.001	Under 12 in. length	1/32	.010	.005	Runout per inch of diam.	.001	.0005	.00025
Screw machines	Under 1.5 in. diam.	.003	.001	.0005	Under 2 in. length	.005	.002	.00075	Under 1.5 in. diam.	.002	.0005	.0002

	Size	*C*	*B*	*A*	*C*	*B*	*A*
Drill and ream	Under 3 in. diam.	.002	.001	.0005	Same as tolerance on hole diameter	1/2 the tolerance on hole diameter	1/4 the tolerance on hole diameter
Boring	Under 3 in. diam.	.001	.0005	.00025			
Hole grinding	Under 3 in. diam.	.001	.0005	.00025			

Operation	Length				Flatness				
	Size	*C*	*B*	*A*	Size		*C*	*B*	*A*
Milling	Slots and splines under 2 in.	.005	.001	.0005	Bed type machine	12	.003	.0015	.001
					Double this for knee type	24	.004	.0025	.0015
						36	.006	.004	.002
Planing	Ways and channels under 12 in.	.005	.002	.001	Length	24	.003	.002	.001
						72	.005	.003	.0015
Surface grinding	Thickness under 6 in. Area 4 x 4	.001	.0003	.0001	Length	6	.001	.0003	.0001
	Area 18 x 18	.003	.001	.0005		24	.003	.001	.0005
	Area 2 x 60	.003	.001	.0005		72	.003	.001	.0005
Scraping	Any length that can be measured	.0005	.0002	.0001	Values per foot of length		.0002	.0001	.00005

The three classes of tolerances may be described as:

C. Practical tolerances which can readily be maintained by an average operator pushing for high production on an average machine. In general time cannot be saved or costs reduced by using more liberal tolerances for these operations.

B. A good operator using a good machine can maintain these limits in production. Tools must be sharpened and wheels trued more often than in (A), and added passes or finishing cuts must be made. Costs will be 15 to 50% higher than for "A" tolerances.

A. These tolerances are about the smallest that should be placed on drawings. This work requires continuous vigilance. Machines must be kept in first-class condition, and fine gages and measuring tools must be available. Before "A" tolerances are specified, need for such precision and willingness to pay the costs should be ascertained.

2. FITS

The degree of tightness or looseness between two parts that are intended to act together is known as the fit of the parts. The character of the fit depends on the use to which it is to be put. Thus the fit between members that move or rotate relative to each other, as a journal rotating in a bearing, is considerably different from the fit which is designed to prevent any relative motion of the fitted members, as, for example, a tire fitted to a locomotive driving-wheel center.

Manufacturers and engineering associations have adopted in the past many different standards for fits to meet their particular needs. For details of these practices, see earlier editions of this book and also Ref. 1. In 1925 the American Standards Association published a standard (B4a-1925) called Tolerances, Allowances and Gages for Metal Fits. In 1947 additional recommendations were made in ASA B4.1-1947, which is Part 1 on Limits and Fits. These two standards are the source of most of the material which follows. For fits in journal bearings, see pp. 12-50 and 12-51, and for fits for ball and roller bearings see pp. 12-85 to 12-92.

TERMS RELATING TO FITS (B4.1-1947).

Nominal Size. The size used for purposes of general identification.

Limits of Size. The maximum and minimum sizes permissible for a specific dimension.

Tolerance. The total permissible variation in size. The tolerance is the difference between the limits of size.

Allowance. A prescribed difference in dimensions of mating parts. It is a minimum clearance or a maximum interference between mating parts.

Clearance Fit. A fit between mating parts having limits of size so prescribed that a clearance always results in assembly.

Interference Fit. A fit between mating parts having limits of size so prescribed that an interference always results in assembly.

Transition Fit. A fit between mating parts having limits of size so prescribed as partially or wholly to overlap, so that either a clearance or an interference may result in assembly.

PREFERRED SIZES (B4.1-1947). To conserve the number of tools and gages required and to limit bar stock to an orderly series of sizes, the following tables of preferred values have been prepared:

Preferred Nominal Sizes

.0100	.0313	.0938	3/16	7/16	11/16	1 1/8	1 5/8	2 1/8	2 5/8	3 1/4
.0125	.0400	.1000	1/4	1/2	3/4	1 1/4	1 3/4	2 1/4	2 3/4	3 1/2
.0156	.0500	1/8	5/16	9/16	7/8	1 3/8	1 7/8	2 3/8	2 7/8	3 3/4
.0200	.0625	5/32	3/8	5/8	1	1 1/2	2	2 1/2	3	4
.0250	.0800									

Preferred Tolerances and Allowances

.0001	.00025	**.0005**	**.0010**	.0015	.0025	.0040	.0060	**.0100**	.0150	.0250
.00015	.0003	.0006	.0012	**.0020**	.0030	**.0050**	.0080	.0120	**.0200**	**.0300**
.0002	.0004	.0008								

Bold-faced values are preferred values.

In using the tables of fits given in the following pages, if possible select nominal sizes which are listed in the preferred nominal sizes table. Do not, for example, call for a 15/16 diameter if 1 can be used; also, design for 3 or 3 1/4 instead of 3 1/8. Tolerances taken from the table of fits may be changed to conform to the preferred tolerances and allowances values. If, for example, "go"-"not-go" gages are available for holes ground standard to plus 0.0005, then the limits for a class 4, 1 diameter hole which are standard to +0.0006 can be reduced to standard to +0.0005.

CLASSIFICATION OF FITS. Fits are classified as follows:

Class 1, Loose Fit, Large Allowance. This fit provides for considerable freedom and embraces certain fits where accuracy is not essential. Examples of its use are the machined fits on agricultural and mining machinery, control apparatus for marine work, machinery in the textile, rubber, and canning industries, and general machinery of similar grades. It is used for strictly interchangeable assembly. Tolerances and allowances are determined by the following formulas, in which d = diameter of fit, inches:

$$\text{Allowance} = 0.0025\sqrt[3]{d^2};\ \text{hole tolerance and shaft tolerance} = 0.0025\sqrt[3]{d}$$

Dimensions are given in Table 1.

Class 2, Free Fit, Liberal Allowance. This fit is designed as a running fit for speeds of 600 rpm or over, and journal pressures of 600 psi or more. Examples of its use are electric generators, engines, machine tool parts, and automotive parts. It is used for strictly interchangeable assembly. Allowances and tolerances are determined by the following formulas:

$$\text{Allowance} = 0.0014\sqrt[3]{d^2};\ \text{hole and shaft tolerance} = 0.0013\sqrt[3]{d}$$

Dimensions are given in Table 1.

Class 3, Medium Fit, Medium Allowance. This fit is designed for running fits under 600 rpm and with journal pressures of less than 600 psi. It also is used for sliding fits, and the more accurate machine tool and automotive parts. It is designed for strictly interchangeable assembly. Allowances and hole tolerances are determined by the following formulas:

$$\text{Allowance} = 0.0009\sqrt[3]{d^2};\ \text{hole tolerance and shaft tolerance} = 0.0008\sqrt[3]{d}$$

Dimensions are given in Table 2.

Class 4, Snug Fit, Zero Allowance. A snug fit is the closest fit that can be assembled by hand. It necessitates work of considerable precision. It is used where no perceptible shake is permitted, and where moving parts are not intended to move freely under load. An example of its use is the assembly of the body and jaws of a drill chuck. It is designed for strictly interchangeable assembly. Allowance = 0.0000. Hole and shaft tolerances are determined by the following formulas:

$$\text{Hole tolerance} = 0.0006\sqrt[3]{d};\ \text{shaft tolerance} = 0.0004\sqrt[3]{d}$$

Dimensions are given in Table 2.

Class 5, Wringing Fit, Zero to Negative Allowance. This fit also is known as a *tunking fit*. It is practically a metal-to-metal fit. Assembly usually is selective and not interchangeable. Examples of its use are locating keys, tongues, or dowels. The selected

* Minimum limit = 0.0000 in. for all sizes. † Plus here denotes clearance or amount of looseness.
‡ Maximum limit = 0.0000 in. for all sizes. § Tightest fit allowance = 0.0000 for all sizes.

average interference of metal is 0.0000 in. Hole and shaft tolerances are determined by these formulas:

$$\text{Hole tolerance} = 0.0006\sqrt[3]{d};\quad \text{shaft tolerance} = 0.0004\sqrt[3]{d}$$

Dimensions are given in Table 3.

Class 6, Tight Fit, Slight Negative Allowance. These fits are used where parts are to be more or less permanently assembled, and light pressure is required in the assembly operation. They are used for drive fits in thin sections, or very long fits in other sections, and also for shrink fits on very light sections. Examples of the use of this fit are jig bushings, and fixed ends of studs for gears, pulleys, rocker arms, in automotive, ordnance, and general machine manufacturing. In this fit, the average interference of metal is the desired condition. It must be obtained by selective assembly, i.e., by mating large shafts in large holes, and small shafts in small holes. In this fit, selected average interference of metal = 0.00025*d*. Hole tolerances and shaft tolerances are given by the formula

$$\text{Tolerance} = 0.0006\sqrt[3]{d}$$

Dimensions are given in Table 3. The stresses set up in the members, and the forces required for making these fits, are given in Table 4. The values of the greatest hole stress in Table 4 are for mean diameters only. For other sizes in the same group, the interference per inch of diameter, and hence the greatest hole stress, varies from the values given by less than 10%. If greater accuracy for intermediate steps is required, the interference per inch of diameter should be computed by the formula given above. The values given in Table 4 are true only when hub diameter equals twice the hole diameter.

Class 7, Medium Force Fit, Negative Allowance. These fits are used where the parts are to be permanently assembled. Considerable pressure is required for assembly. They are the tightest fits recommended for cast-iron holes or external members, since they will

† Minus here denotes interference of metal or negative allowance.
‡ Plus here denotes clearance or amount of looseness.

stress cast iron to its elastic limit. Examples of the use of this class of fit are the attachment to their axles or shafts of locomotive and car wheels, generator and motor armatures, and engine crank disks. This class of fit also is used as a shrink fit on medium sections or long fits. These fits are used for selective assembly only. Selected average interference of metal = $0.0005d$. The shaft and hole tolerances are determined by the formula

$$\text{Tolerance} = 0.0006\sqrt[3]{d}$$

Dimensions are given in Table 5. Stresses set up in the parts, and the pressure required to make the fits, are given in Table 6. The values given in Table 6 for stress and force are true only when the hub diameter equals twice the hole diameter. The values of greatest hole stress are for mean diameter sizes only. For other sizes in the group, the interference per inch of diameter, and hence the greatest hole stress, will vary from the values given by less than 10%. If greater accuracy for intermediate steps is required, the interference per inch of diameter should be computed by the formula given above.

* Interference of metal on selected fits, all sizes, = 0.00025 in.
† Greatest stress in hole on selected fits, all sizes, = 7250 lb. per sq. in.
‡ Greatest stress in hole on selected fits, all sizes, = 2608 lb. per sq. in.
§ A = allowance; d = mean size.

Class 8, Heavy Force and Shrink Fit, Considerable Negative Allowance. These fits are used for steel holes where the metal can be highly stressed without exceeding its elastic limit. They cause excessive stress in cast-iron holes. Shrink fits are used where heavy force fits are impracticable, as on locomotive wheel tires and heavy crank disks. They are for selective assembly only. Selected average interference of metal = $0.001d$. Hole and shaft tolerances are given by the formula

$$\text{Tolerance} = 0.0006\sqrt[3]{d}$$

Dimensions are given in Table 7. Stresses set up by, and the force required to make these fits, are given in Table 8. The values given in Table 8 for stress and force are true only when the hub diameter equals twice the hole diameter. The values of the greatest hole stress are for mean diameter sizes only. For other sizes in the group, the interference per inch of diameter, and hence the greatest hole stress, varies from the values given by less than 10%. If greater accuracy for intermediate steps is required, the interference per inch of diameter should be computed by the formula given above.

STRESSES RESULTING FROM FORCE FITS. In any force or shrink fit, the metal of the fitted member is deformed by an amount equal to the interference of metal between the external and internal members. Discussions of the stress set up by this deformation usually are based on the assumption that the materials are elastic and follow Hooke's law. A. Lewis Jenkins (*Am. Mach.*, March 4, 1915) shows that for the usual combination of a cast-iron hub shrunk on a steel shaft, Hooke's law does not apply to the cast-iron hub. From a study of a wide variety of force and shrink fits, he deduced the following equations:

For cast-iron hubs on steel shafts:

$$p = \frac{102{,}900{,}000(e/r_2)}{7.16 + (r_3/r_2)}$$

* Minus here denotes interference of metal or negative allowance.
† Plus here denotes clearance or amount of looseness.

For steel hubs on steel shafts:

$$p = \frac{30{,}000{,}000(e/r_2)[(r_3/r_2)^2 - 1]}{2(r_3/r_2)^2}$$

where p = the unit stress between shaft and hub; r_2 = common radius of fitted shaft and hub; r_3 = external radius of hub; e = total deformation of shaft and hub in pressing $= r_s - r_h$; r_s, r_h = respectively, external radius of shaft and internal radius of hub before pressing.

Table 6. Stresses and Forces for Medium Force Fits, Class 7

A.S.A. B4a–1925

Force values are for fits 1 in. long. For longer fits multiply tabular values by length of fit in inches

			Stress = 29,000,000A/d§		Stress = 10,432,000A/d§		Force = 1298 A §			Force = 747.2A §		

NOTE 1. No values are given for sizes 1/8 in. to 1 1/4 in. inclusive, because of the absence of interference of metal, due to the smallest shaft member being smaller than the largest hole member.

* Interference on selected fits, all sizes, = 0.0005 in.

† Greatest hole stress on selected fits, all sizes, = 14,500 lb. per sq. in.

‡ Greatest hole stress on selected fits, all sizes, = 5216 lb. per sq. in.

§ A = allowance; d = mean size.

* Minus here denotes interference of metal or negative allowance.
† Plus here denotes clearance or amount of looseness.

In designing force and shrink fits, the interference e usually is assumed. The resulting stress then should be calculated to make sure that the elastic limit of the material is not exceeded.

DESIGN DATA. The design of press and shrink fit assemblies is well summarized in the design data sheets prepared by O. J. Horger and C. W. Nelson (Ref. 2).

TEMPERATURES FOR SHRINKAGE FITS. The temperature to which the outer member in a shrinkage fit must be heated in order to assemble the parts depends upon the coefficient of linear expansion of the metal. For wrought iron and steel this is about 0.0000065 for each °F and for cast iron it is 0.0000062. Low redness corresponds to about 900 F and hence causes an expansion of the bore of about 0.005 in. per in. of diameter.

EXPANSION FITS. It is sometimes more convenient to contract the shaft than to expand the ring when assembling members for an interference fit. Dry ice (solid CO_2)

Table 8. Stresses and Forces for Heavy Force and Shrink Fits, Class 8

A.S.A. B4a–1925

Force values are for fits 1 in. long. For longer fits, multiply tabular values by length of fit in inches

				Stress = 29,000,000 A/d *			Force = 1298A *		

* A = allowance; d = mean size.

NOTE 1. No values are given for sizes 1/8 in. to 1/2 in. inclusive because of the absence of interference of metal, due to the smallest shaft member being smaller than the largest hole member.

in alcohol, or liquid air, may be used for the cooling medium. Dry ice has a temperature of −110 F, and from a 70 F room temperature can contract steel about 0.001 in. per in. of diameter. Liquid air boils at −310 F, and from a 70 F room can contract steel better than 0.002 in. per in. of diameter. (See Ref. 3.)

BASIC SHAFT SYSTEM. The fits just tabulated have been set up using a basic hole or one that always has the basic size as the minimum limit of the hole. The allowance for various fits is obtained by varying the dimensions of the shaft. Now the same fit or the same degree of clearance or interference can be obtained using a basic shaft system in which the maximum limit of the shaft is the basic size and where the allowance for various fits is obtained by varying the hole size. To use the basic shaft system, adopt the allowance or tightest fit figures from the tables of fits and work out limits to give these allowances.

DIMENSIONAL MEASUREMENTS

By Ermand L. Watelet

Industrial dimensional measurements may be divided into three classifications: nonprecision, precision, and high precision. The range of precision in each group, however, is quite wide and depends on the inherent accuracy of the device plus the expertness of the user. In the precision and high-precision groups additional factors of temperature, measuring pressure, friction, and cleanliness affect the amount of precision obtainable. In general, nonprecision measurements are made with an accuracy of 0.015 to 0.001 in., precision measurements within an accuracy of 0.001 to 0.0001 in., and high precision 0.0001 in. or less.

3. NONPRECISION MEASURING DEVICES

THE STEEL RULE or scale, ordinarily made in lengths of 6 in. or multiples thereof up to 6 ft, is perhaps the most commonly used device for direct measurements in the shop. It is made with graduations 0.005 to 0.010 in. wide, etched in polished tempered steel and is divided into inches subdivided into 8ths, 16ths, 32nds or 64ths. Decimal rules are divided into inches subdivided into 10ths, 20ths, 50ths or 100ths. Few rules are divided into 100ths because such closely spaced graduations are difficult to read. Although rules of good quality are inherently accurate beyond the precision to which they are used, the average person can use them only to an accuracy of about 0.010 in. Experts, with the aid of an eyeglass, can estimate to as close as 0.002 or 0.003 in.

THE HOOK RULE is a plain rule to which has been added an adjustable member flush with one end of the rule and projecting beyond the measuring edge for the purpose of conveniently making a measurement from a shoulder or edge without the necessity of setting the first end by eye. It is particularly useful in measuring from a hidden edge.

THE RULE DEPTH GAGE is a narrow rule equipped with a sliding head having a working surface at right angles to the rule. The head is provided with clamping means for locking it in position when a measurement has been made. This device is used for measuring the depth of holes and slots or determining the distance from a shoulder to another point.

THE CALIPER RULE has a fixed jaw at one end of the scale and a sliding jaw movable along the scale. The measuring faces of the jaws are parallel to each other and square with the edge of the rule. For the measurement of outside diameters and thicknesses, it affords a greater degree of accuracy than a plain rule because graduations are more easily sighted from the edge of the movable jaw. The ends or nibs of the jaws are rounded and held to a fixed width for the purpose of making internal measurements. An index line is marked on the movable jaw for the purpose of indicating internal measurements. The movable jaw is provided with locking means for preserving a specific setting.

THE SHRINK RULE. In the making of metal castings the metal contracts or shrinks as it cools. Suitable allowance must therefore be made in the dimensions of the pattern used to make the mold in which the molten metal is poured. The shrinkage value for a specific metal is fairly constant, and it is possible therefore to graduate shrink rules to give shrinkage allowances directly. Thus the pattern maker can set his pattern sizes directly from the dimensions on the drawing by the use of a shrink rule without the necessity of computing shrinkage allowance. The graduations on a shrink rule, while indicated in inches and fractions, are actually greater. Thus, 1 in. on a shrink rule for cast iron which has a shrinkage of $^1/_8$ in. per ft is actually 1.0105 in. long.

CALIPERS. It is often necessary to make nonprecision measurements which cannot be made directly with a rule. For instance, it would not be possible to determine the diameter of a piece being turned in a lathe with a rule.` For applications of this type a caliper, comprising a pair of legs hinged at one end and made adjustable to measure at the free ends, is frequently used. Since calipers are not graduated, the actual measurement is determined by referring the setting or space between the ends of the legs to a graduated rule.

Outside spring calipers have the measuring ends of the legs curving inwardly so that no part of the legs except the ends ever contact the part being measured.

Inside spring calipers are similar except that the measuring ends of the legs curve outwardly and are used to measure inside dimensions such as the diameter of a hole. Spring calipers are limited in size to about 8 in.

Firm joint calipers, both outside and inside types, are similar in construction to the spring type except that the legs are held in a set position by means of a friction joint. Firm joint calipers are particularly convenient in making large measurements and are therefore made in sizes up to 24 in. or larger.

Hermaphrodite calipers have one inside or outside leg and one leg terminating in a divider point. They are used for such layout work as scribing a line parallel to a shoulder or edge, and may be either of the spring or firm joint type.

Transfer calipers are used for making measurements of recesses or diameters which are larger than the opening through which the calipers must be inserted. They are provided with an auxiliary arm against which one leg bears, thereby allowing collapsing of the leg for removal from the hole while preserving the measurement.

DIVIDERS are calipers with both legs terminating in sharp points, used for scribing arcs and circles as well as transferring and making measurements. They may be either of the spring or the firm joint types.

BEAM TRAMMELS, which are used in sizes beyond the range of dividers, consist of a long bar on which two arms or trammels slide. The arms terminate in one of a variety of points and are arranged to be clamped in the desired position. A fine adjustment may be provided with one of the legs for easy setting.

4. PRECISION MEASURING DEVICES

THE VERNIER (Fig. 1), consists of a fixed scale and a vernier scale, which is movable in relation to the former. The vernier scale makes possible the accurate reading of a measurement to a fractional part of the smallest division on the fixed scale and therefore converts a scale into a precision device. Although a vernier scale can theoretically be designed to indicate to very small fractions of length, it is limited practically to about 0.001 in. when applied to simple scales.

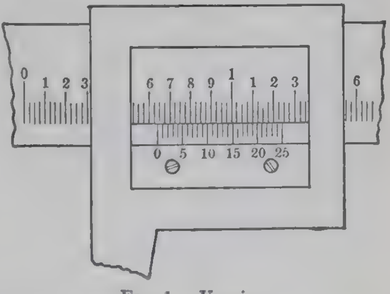

FIG. 1. Vernier.

EXAMPLE. The number of graduations on the vernier scale is equal to the number of parts into which the smallest graduations of the fixed scale may be subdivided. The total length of these graduations is made equal to the length of an equivalent number on the fixed scale minus one. For instance, a typical vernier (Fig. 1) has a fixed scale graduated into 0.025 in. or $^{25}/_{1000}$ in. It is desired to read directly to 0.001 in., which is $^{1}/_{25}$ of one graduation. Therefore, the vernier scale is graduated into 25 divisions, the total length of which is equal to 24 divisions on the fixed scale. Thus, the difference between the length of one graduation on the fixed scale and that of one division on the vernier scale is $^{1}/_{25}$ of 0.025 in. or 0.001 in. The first or zero graduation on the vernier scale is the index line, i.e., the point at which the measurement is observed. If the zero line on the vernier scale coincides with a graduation on the fixed scale, the measurement is to an even 0.025 in. If the zero line is between graduations on the fixed scale, the remainder of the measurement is determined by noting the number of the vernier scale graduation that coincides with a graduation on the fixed scale. This number is the number of $^{1}/_{1000}$ in. which must be added to the reading on the fixed scale.

In Fig. 1, the reading on the fixed scale is 0.625 + in. (Each small graduation on the scale = 0.025 in.) Graduation 19 (representing $^{19}/_{1000}$ or 0.019) on the vernier scale coincides with a graduation on the fixed scale. Thus the reading is $0.625 + 0.019 = 0.644$ in.

THE VERNIER CALIPER is similar in principle to the caliper rule described before except that a vernier scale is added for making precision measurements. In addition, much greater refinements are made in the quality of the device with respect to the accuracy of the graduations, the squareness and parallelism of the jaws, and the fit of the movable jaw on the bar. The width of graduations on vernier devices is smaller than those on rules, being of the order of 0.003 or 0.004 in. It will be evident that in order to use the vernier caliper to the observed accuracy some degree of skill and judgment is necessary. The vernier caliper is used for making inside as well as outside measurements. The ends of the jaws are provided with nibs that are ground on the outside to a radius less than the smallest inside diameter which may be measured.

Separate vernier plates and graduations are provided for inside and outside measurements.

THE VERNIER HEIGHT GAGE is used to make measurements of height to 0.001 in. above a plane surface. In general, it is used on a commercial surface plate which has the required accurate flat surface. The vernier height gage consists of a vertical graduated bar, a base, and a movable jaw. The bottom of the base is lapped flat and square with the bar. The movable jaw has its upper and lower surfaces finished parallel to the bottom of the base for making measurements over or under a part. It is attached to a slide which carries a vernier plate. The slide is provided with a clamp screw and an additional adjusting slide for making fine adjustments. A combination marker and extension is furnished for clamping to the jaw and is used for scribing lines on work or for making measurements which cannot be reached by the jaw.

THE VERNIER DEPTH GAGE is similar to the rule depth gage except for the addition of a vernier scale for reading to 0.001 in., better accuracy of graduations, and refinement of construction.

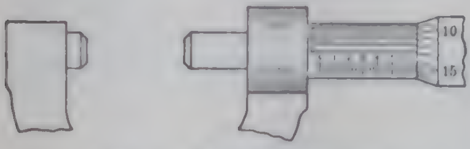

Fig. 2. Vernier micrometer.

THE MICROMETER is probably the most commonly used precision measuring device in industry for obtaining measurements of the order of 0.001 to 0.0001 in. Its measuring accuracy is based on an accurate screw and a fixed nut. The micrometer (Fig. 2) is composed of a U-shaped frame, the end of one leg of which carries a fixed anvil, the other leg carrying a tubular member or barrel. The micrometer nut is fixed in the barrel and is slotted and provided with a tapered thread and nut at its outer end to allow adjustment for wear. The measuring spindle and screw are integral, being supported on the nut at the threaded end and in an accurately fitted hole in the frame at the spindle end. To the outer end of the spindle is fastened a shell or thimble which extends over and turns around the barrel. The measurement is made between the faces of the anvil and spindle.

Example. The screw in the standard micrometer has 40 threads per inch and thus advances 1/40 in. per turn or 0.025 in. The beveled edge of the thimble is graduated into 25 equal divisions to allow measurements of 1/25 of a turn or 0.001 in. The barrel is graduated along its length into divisions of 0.1 in. and subdivided to 0.025. Thus, one turn of the thimble moves one division on the barrel. A longitudinal line on the barrel serves as an index for the thimble graduations. A vernier scale (Fig. 2) may be added to the barrel in conjunction with the thimble graduations. Ten graduations, equal to nine on the thimble, enable subdivision of the thimble graduations to 0.0001 in. The total measurement is equal to the reading on the barrel plus the reading on the thimble plus the reading of the vernier.

The thimble of the micrometer in Fig. 2 has uncovered 6 main divisions and 3 subdivisions on the barrel. The scale on the thimble shows that it has been turned through 12+ divisions past the index line on the barrel. The third line on the vernier scale coincides with a line on the thimble scale. The reading of the micrometer then is:

Scale on barrel	0.6 + (3 × 0.025) =	0.675
Scale on thimble	12 × 0.001 =	0.012
Scale on vernier	0.0003 =	0.0003
Micrometer reading		0.6873

The Ratchet Stop. In the use of the micrometer the measuring pressure is dependent on the operator's sense of "feel." Errors of 0.0001 to 0.0003 in. may be introduced in a measurement as a result of this factor. In order to overcome this source of error, a device known as a ratchet stop is provided for use with the micrometer. Attached to the end of the thimble, it serves as a constant-torque turning means. The outer knurled member, when turned, exerts a turning force on the thimble through ratchet teeth under spring pressure. When the spindle and anvil contact the part to be measured and the correct pressure has been reached, the ratchet teeth will slip, preventing further pressure from being applied. Ratchet stops are set to give a measuring pressure of approximately 25 lb per sq in. of spindle face area.

INSIDE MICROMETERS are used for measuring the diameters of holes and other inside dimensions. Two general types are in use. The first, an inside micrometer caliper for measuring small inside dimensions of 0.2 to 1 in., is provided with two jaws, one fastened to the end of the spindle, the other to the barrel of the micrometer. The spindle and screw are separate parts of this device.

The spindle moves longitudinally with the screw but is restrained from turning since the jaws must remain parallel at all measuring positions. The measurement is made on the outside of nibs provided at the ends of the jaws.

For measuring holes and inside dimensions larger than 1 in. and up to several feet, inside micrometers are provided that measure from anvils placed at the ends of thimble and barrel. By means of interchangeable measuring rods a wide range of measurements is possible. The micrometer head has a range of 1 in. whereas the rods are made in multiples of 1 in. so that measurements are possible from minimum to maximum size by 0.001-in. intervals.

THE MICROMETER DEPTH GAGE is used for measuring the depth of holes and slots or the distance from one surface to another. It is similar in general construction to the rule depth gage and vernier depth gage except that a micrometer head is used for measuring. A base whose lower surface is at right angles to the micrometer axis is fastened to the micrometer barrel and is used as the reference point. A measuring rod is encased in the hollow screw and is clamped by means of a chuck at the end of the thimble at one of several scribed graduations on the rod. The distance between the graduations is equal to the micrometer screw movement so that a range of measurements from zero to several inches by intervals of 0.001 in. is possible by clamping the rod progressively at the separate scribed graduations. Each graduation on the rod is a V groove into which fingers in the chuck fit for accurately locating the rod.

Other types of micrometer depth gages are made with several interchangeable measuring rods of different lengths in contrast to a single rod with spaced grooves.

THE DIAL INDICATOR (Fig. 3) is an instrument in which the movement of a spring-loaded measuring spindle is magnified by means of a rack and train of gears which actuate a pointer on a graduated dial. Typical scale graduations are 0.001, 0.0005, and 0.0001 in. for various types and sizes while the magnification varies from about 50 to one to 1250 to one. The rim of the dial or bezel is rotatable so that for a certain setting the zero on the scale may be brought opposite the position of the pointer for convenient reading. Although the dial indicator is a direct-measuring type of device, it is commonly used as a comparator for determining the variations of a measurement from a standard figure.

The dial indicator has many common uses. It may be used as a means of checking runout or out-of-roundness of a piece rotated between centers or to check the trueness of the rotating part of a machine such as the revolving center of a lathe. In these applications the indicator is fixed to a stationary part of the machine either by a clamp or by means of a heavy base to which it is attached. In a similar manner it may be used to set or check the parallelism of one surface with respect to another. When mounted to a base and upright commonly known as a *test set*, it may be used on a surface plate to test for size, straightness, and parallelism of parts. Built-in dial indicators are frequently used in such devices as calipers, snap gages, bore gages, thickness gages, depth gages, height gages, and bench comparators for determining variations in size from a master or standard.

5. HIGH-PRECISION MEASUREMENTS

MEASURING MACHINES are used for making measurements where the accuracy must be maintained to better than 0.0001 in. or of the order of 0.00001 in. Such machines are very rarely used in production work, but are used for measuring master gages and standards, which are in turn used to check production gages such as master plug, taper plug, and thread gages. In making measurements of the order of 0.0001 to 0.00001 in., it is of utmost importance that control of the measuring pressure be made, since slight variations in pressure will cause errors in the readings too large to allow the accuracy required. For this reason, measuring machines must be provided with pressure control and high-magnification indicators which determine when the exact pressure has been reached. Furthermore, since the dimension of a part varies with the temperature in accordance with its temperature coefficient, it is necessary to measure parts at a specific temperature in order that all measurements shall be consistent. For this reason, 68 F has been established as the standard temperature at which fine measurements must be made. Measuring machines should be used where the temperature is maintained constant at the above value.

A TYPICAL MACHINE, made by the Pratt & Whitney Company (Fig. 4), consists of a heavy bed *A* designed for stability and elimination of distortion, a master bar *B* fastened to the bed and containing fine, accurately spaced lines one inch apart on polished steel plugs, a measuring head *C* with a 1-in. range micrometer screw graduated to 0.0001 in., having a vernier making possible readings to 0.00001 in., a microscope *D* fixed to the measuring head and focused on the master bar for setting to even inches, and a tailstock *E* with adjustable measuring pressure and a high magnification indicator for determining the exact measuring pressure.

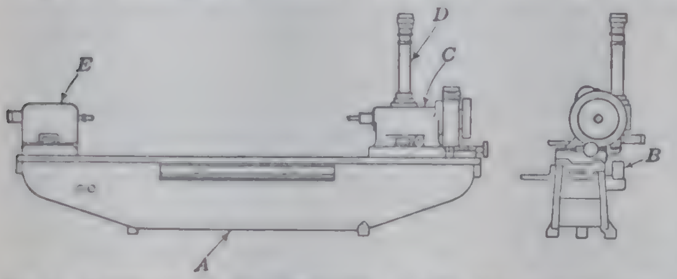

FIG. 4. Measuring machine. (Courtesy of Pratt and Whitney Division, Niles Bement Pond)

In use, the machine is first set to zero. This is done by moving the measuring head until the microscope is focused on the zero line on the master bar and setting the micrometer dial to zero. The tailstock is moved and clamped when its measuring anvil contacts the anvil on the measuring head. The micrometer dial is moved slightly until the pressure indicator is on zero. Finally, the vernier on the micrometer dial is set to zero. On making a measurement the headstock is set so that the microscope is focused on the nearest higher inch line. The part to be measured is supported between the anvils and the micrometer dial turned until the anvils contact the part and the pressure indicator is on zero. The measurement to the nearest 0.00001 in. is then read on the micrometer dial.

THE INTERFEROMETER is an apparatus for making measurements by the use of light waves. The wavelength of monochromatic light emitted by the incandescent gas of an element is the best known natural standard of length. Under constant atmospheric conditions the length of the wave of such a light is always identical for a given substance. If the light from the incandescent gas of an element is observed in the spectrograph it will be found to consist of colors of several frequencies. These colors, which appear as narrow lines on the spectrum, are characteristic of the element. Actually each color is not truly monochromatic, that is, it does not have a single frequency but is composed of several slightly different frequencies. One of the spectrum lines which is most nearly monochromatic is the red radiation of the element cadmium, whose wavelength has been determined in terms of the standard meter and used to make precision measurements. The wavelength of the red radiation of cadmium is 0.000638+ mm.

DETAILS OF THE METHOD by which the wavelength of light is used to make measurements with the interferometer is beyond the scope of this chapter, but the principle may be briefly explained. Light is an electromagnetic disturbance the characteristics of which may be graphically represented by a sine wave whose wavelength λ and frequency are characteristic of the color of the light. The speed of light in air, 186,000 miles per second, is the same for all colors, but is reduced when the light passes through another medium such as glass. If a ray of light passes through two points and it were possible to count the number of wavelengths occupying the distance between them, a measure of the distance could be obtained. This cannot be done directly, since the only effect of light upon the human eye is the sensation of color and intensity. However, by means of the phenomenon of light interference, the interferometer can be used to determine the number of wavelengths of light between two points and, consequently, the measurement. If two rays of light of equal wavelength arrive at a given point in phase, that is, with either the crests or the troughs of the waves in unison, the intensities of the rays are additive, and brilliance results. If, however, the rays are out of phase and the crest of one wave coincides with a trough of another wave, interference occurs, the two intensities cancel each other, and darkness results. In the former case the difference in path lengths of the two rays is equal to a whole number of wavelengths; in the latter the difference is an odd number of half wavelengths.

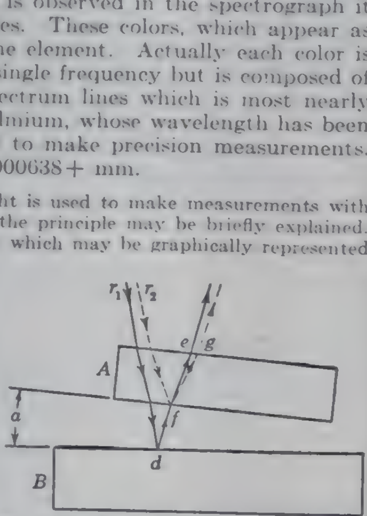

FIG. 5. Principle of the interferometer.

In Fig. 5, *A* is a transparent glass member known as an optical flat whose lower surface is truly flat. *B* is a member under test whose upper surface is also truly flat. r_1 and r_2 are rays from a source of light striking the glass at an angle. A portion of the light represented by r_1 passes through the glass and is reflected from the upper surface of *B* at the point *d*, the path of the reflected light being

df. Another portion of the light represented by r_2 is reflected from the lower surface of A at point f, the path of the reflected light being fg. At the point f, therefore, portions of each ray coincide; and since a portion of r_1 traveled an additional distance through the air from the lower surface of A to the upper surface of B and back to A, it differs from that portion of r_2 reflected at the lower surface of A by a whole or fractional number of wavelengths. Assuming that the difference is an odd number of half wavelengths, interference will occur at f. In practice a large source of light would cause an infinite number of parallel rays to strike the optical flat. If the surfaces of A and B are perfectly parallel, the result of interference is a solid dark color at the lower surface of A when viewed from above. If A and B are at a slight inclination a to each other, a series of straight alternate light and dark bands is seen, as shown in Fig. 6. These are known as interference fringes. It should be noted that the change from light to dark bands is not as sharp as indicated in Fig. 6 but occurs gradually. The distance d between two dark bands represents a change in thickness of the wedge of air between A and B of one-half wavelength of light. The wavelength of light as furnished by commercial monochromatic light devices is 0.0000232 in. Viewed in such a light, the change in thickness would be 0.0000116 in. By counting the whole and fractional number of bands appearing and multiplying by 0.0000116, the total difference in thickness of the wedge of air is obtained. This will indicate to the reader a method of comparing the length of slightly different specimens. If the member B is moved in a direction perpendicular to its upper surface, the bands will be seen to move across the field of view. The number of bands passing a given reference point multiplied by one-half wavelength of light is equivalent to the movement. If the surface of B is not flat, the interference bands will be irregular instead of straight, will describe points of equal elevation much as contour lines on a topographical map. In this manner the exact deviation from flatness of a piece may be determined.

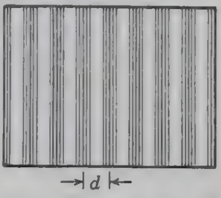

FIG. 6. Interpretation of interferometer bands.

Thus by use of the foregoing principles, the interferometer, using a very accurate optical system of lenses and mirrors, can make absolute measurements of length, comparisons of length, and deviations from flatness.

The simplest and most common use of light interference measurements is with the well-known optical flats. These are commercial glass disks made accurately flat on the sides. Together with the use of a monochromatic light source and gage blocks, the optical flat may be used to compare lengths in the manner described above. They are commonly used also for determination of flatness. It is to be noted that the surfaces of the parts being measured must be highly polished or lapped in order for interference fringes to appear.

For further information on the interferometer, see Refs. 1–4.

PRECISION GAGE BLOCKS are the most accurate commercial standards of length made. They consist of hardened steel blocks of rectangular or square cross section whose two opposite measuring faces are lapped flat and parallel to each other, and are held to a dimensional accuracy of a few millionths of an inch for lengths up to one inch and of an equivalent amount per inch for lengths over one inch. This accuracy requires the use of alloy tool steel of exceptional stability, careful heat treatment, and proper seasoning. Gage blocks are made in lengths of 0.010 in. to 20 in. or more and are furnished in sets having a variety of sizes. By using the blocks singly or in combinations, a large variety of sizes is possible. With sets having sufficient specific sizes, it is possible to make combination sizes over a range in increments of 0.0001 in. For example, a typical set of 81 blocks is divided into the following:

1 Block—0.050 in.
10 Blocks—0.100 in. to 0.1009 in. by 0.0001-in. steps
50 Blocks—0.101 in. to 0.150 in. by 0.001-in. steps
16 Blocks—0.200 in. to 0.950 in. by 0.050-in. steps
4 Blocks—1.000 in. to 4.000 in. by 1-in. steps

With such a set it is possible to obtain any dimension from 0.100 in. to 0.200 in. in increments of 0.001 in., and any dimension from 0.200 in. to over 10 in. in increments of 0.0001 in.

The utility of gage blocks in combinations is greatly enhanced by their ability to adhere to each other when suitably wrung together. This quality is due to the intimacy of contact of two highly finished and flat surfaces. The force of this adherence is sufficient to more than support the weight of several blocks thus held together. The errors due to joining several blocks together are so small as to be negligible, being in the order of a fraction of one millionth inch per joint.

Gage blocks are used extensively for setting measurements of reference and master gages, for calibration of measuring instruments, as masters for comparator instruments, and for establishing any high-precision measurement. With the use of suitable attachments and holders, gage blocks may be built up into outside and inside caliper combinations.

COMPARATORS. The comparator is a device which measures a dimension to an accuracy of 0.0001 in. to better than 0.00001 in., by comparison with a known standard as against the direct measuring types described heretofore. It is used for rapid inspection of parts in production as well as for making a variety of precision measurements. Its main element is a high-magnification low-range measuring head or indicator having a constant measuring pressure. The magnification is the ratio of the actual size of scale indication to the movement of a measuring spindle. For instance, a comparator whose scale has graduations 0.10 in. apart representing a spindle movement of 0.0001 in. would have a magnification of 0.10/0.0001 = 1000. In consequence of the limited space available on a scale, it is obvious that the range of the measuring head is, of necessity, small. It is for this reason that the device can be used only to compare the size of a part with a known standard of the same nominal size, its scale indicating by how many units the part is large or small. The comparing range, however, may be made as large as desired simply by moving the measuring head mechanically with respect to a reference anvil. Several types of commercial comparators are made. Mechanically, they all have the same basic elements but differ in refinements and in the principle used to obtain magnification.

Mechanical comparators use a measuring head or indicator which obtains its sensitivity from some form of mechanical multiplying system such as a gear train, levers, or other means. The conventional dial indicator belongs in this category. Because of practical limitations in mechanical movements, magnifications in excess of about 1000 are obtained by other methods.

Optical comparators employ the multiplying effect of an optical mirror and lens system. In one such scheme a measuring point is fastened to a mirror in such a manner that movement of the point causes tilting of the mirror. Light from an illuminated accurate glass scale is reflected from the mirror through an objective lens and is projected on a screen where a magnified image appears. Movement of the measuring point causes the scale to move past a fixed reference line on the screen, and thus indicates the amount of movement. A comparator made by the Sheffield Corporation uses part mechanical and part optical means for magnification. In this device movement of the measuring point causes the movement of an arm through an amplifying reed mechanism. The arm carries a target which interrupts a light beam projected through a lens system and casts a shadow on a scale. Movement of the target is amplified by the reed mechanism, and movement of its shadow further magnified by the optical system. Magnifications up to 20,000 are obtained by this method.

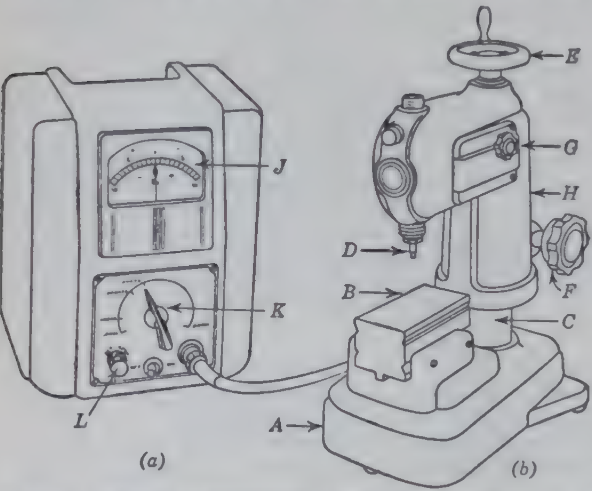

FIG. 7. Electronic comparator. (Courtesy of Brown and Sharpe Manufacturing Co.)

The electronic comparator, shown in Fig. 7, made by the Brown & Sharpe Manufacturing Company, obtains magnification through electrical and electronic means. It is made in two units, the comparator *b*, and the electronic amplifier and indicator *a*. The comparator consists of a base *A* to which is fastened an anvil *B* and an upright column *C*. The upper surface of the anvil is accurately lapped to a high degree of flatness. The head *H* is movable vertically on the column *C* and carries the measuring spindle *D* and the gaging mechanism within. Movement of the measuring spindle causes the deflection of a sensitive element employing four bonded type resistance wire strain gages which are all active and connected in a Wheatstone bridge circuit. The bridge circuit is fed with a low-voltage alternating current, and its output signal is determined by the amount of unbalance of the bridge as determined by the spindle movement. The output signal is then amplified through the electronic circuit of amplifier *a* and impressed upon a sensitive galvanometer whose scale *J* is calibrated to indicate the spindle movement. By means of selector *K* the graduations of the scale may be made to equal any value from 0.0001 to 0.00001 in.

In the use of the comparator, a master is placed on the anvil *B* and the head lowered by means of the handwheel E until the spindle D contacts the master. The head is then locked by means of clamp F. Further adjustment to bring the pointer of the scale near zero is made by knob G on the comparator, and final zero adjustment by knob L on the amplifier. The master is removed, and the instrument is ready for use in checking the work. Instruments of this type may be adapted with the use of additional equipment for automatically or semi-automatically sorting parts into categories of several sizes, such as small, large, and within tolerance.

Air comparators or air gages have been developed and are used mainly for the measurement of internal diameters. The measuring member is a cylindrical plug having a central air duct which terminates in one or more jets on the outside diameter of the plug. A narrow circular land surrounds the jet opening; a circular groove surrounds the land. Suitable clearance cuts on the periphery of the plug serve to allow free escape of air once it has passed between the jet land and the wall of the hole. If air is fed to the jets under constant pressure, the rate of air escape is proportional to the clearance between the jets and the sides of the hole being checked. In other words, the rate of flow of air is proportional to the size of hole. The relationship, however, is true only for small clearances between the plug jets and the hole. For this reason, the measuring range is seldom made over 0.004 to 0.005 in.

Two types of air circuits are used to convert the rate of air escape to an indicated measurement. The first type measures the back pressure caused by limiting the discharge of air through the jets. This comparator receives compressed air from a source and passes it through a filter and pressure regulator. From the regulator the air passes through a restricting orifice to a pressure indicator and the gaging plug. The scale of the pressure indicator is calibrated in graduations representing parts of an inch.

The second type of air circuit uses the *rate of flow principle*. Figure 8 shows an air comparator made by the Sheffield Corporation, which incorporates this principle. Compressed air enters the gage through a filter and pressure regulator and passes directly through the vertical transparent indicator tube A to the gaging plug B. The indicator tube hole is tapered slightly, the small end being at the bottom. An indicator float is free to move up and down in the tube and will adjust itself at some position corresponding to the velocity, or rate of flow of air through the tube and gaging plug. The gage is set to maximum and minimum rings representing the limits of tolerance of a hole, and adjustable markers are set at the points at which the float comes to rest. For all parts within tolerance the float will come to rest at some point between the two markers.

Air gages are convenient for checking taper, bell mouth, and out-of-round as well as size of holes. Since the gaging members or jets do not contact the part, there is no need for critical positioning of the gaging plug.

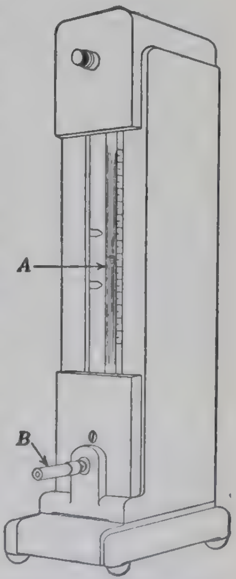

FIG. 8. Air comparator. (Courtesy of Sheffield Corp.)

The optical projection comparator is used for measuring curves, contours, radii, short angles, thread forms, gear tooth forms, etc., which are either impossible or impractical to measure with linear measuring devices. A beam of light is directed against that portion of a part being checked, the resulting shadow of which is magnified and projected upon a ground glass screen. The shadow is brought into coincidence with a master magnified outline of the particular form engraved or otherwise impressed upon a transparent sheet placed over the screen. Deviations of the part from standard can thus easily be seen. Common magnifications used are 20 : 1 and 62.5 : 1, the latter value being convenient in that 0.001 in. appears as $^1/_{16}$ in. on the screen. A measurement from one point to another of a part may be made by moving the table on which the part is held with a micrometer screw so that the image on the screen moves past a fixed reference line on the screen, and the amount of movement is noted on the micrometer. The device is arranged so that both lateral and vertical measurements are possible.

6. MEASUREMENT OF ANGLES

THE UNIVERSAL BEVEL PROTRACTOR (Fig. 9) is commonly used for measuring and setting angles. It consists of a body graduated through a complete circle in quadrants of 0 to 90 degrees. A dial carrying a vernier scale can be rotated about the center of the body. The main scale and vernier are so graduated as to enable readings to 5 min of arc. The angular measurement is made between a blade clamped to the dial and one of two projecting members of the body. This type of protractor can be used to measure inside as well as outside angles. In using the instrument care must be taken that it is held at right angles to the planes of the angle being measured.

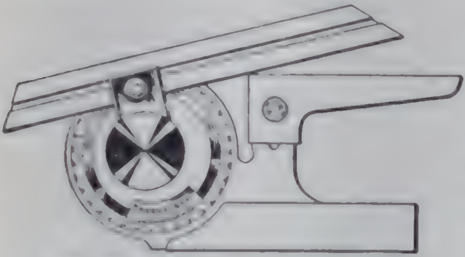

FIG. 9. Universal bevel protractor.

THE SINE BAR is a device used for accurately setting and checking angles by linear measurements. A typical arrangement is shown in Fig. 10. A bar *B*, whose upper surface is ground and lapped straight and flat, is machined to receive two rolls *R*, as shown. The diameters of the rolls and their distances from the top surface of the bar are made as nearly alike as possible. The distance *L* is made to equal either 5 or 10 in. The bar is set to a desired angle *a* by placing it with one roll on the plane surface *S* and the second roll on a gage block *G* having a specific length. Since the diameters of the rolls are equal, the length of *G* is equal to *H*, and $H = L \sin a$. The necessary length of *G* is determined, therefore, by multiplying the sine of the desired angle by *L*. A 5-in. sine bar whose various dimensions are accurate to 0.0001 in., together with gage blocks, can be relied upon to set small angles to an accuracy of a few seconds of arc. The error rapidly increases, however, when settings of large angles approaching 90 degrees are made. For this reason, when large angles are required, it is best if possible to set to the complement of the angle.

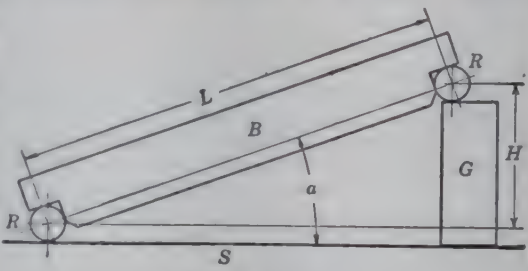

FIG. 10. Sine bar.

7. SCREW-THREAD MEASUREMENTS

The important measurements of screw threads are those made of the pitch diameter, the angle of thread, and the lead. The pitch diameter is the diameter at which the thread thickness is equal to the space between the threads. The angle of thread is the included angle between the sides of adjacent threads measured in the same plane as the axis of the screw. The lead is the distance advanced along the screw axis in one turn of the thread. For single-thread screws, the lead is equivalent to the pitch, or distance between centers of adjacent threads.

THREAD MICROMETER. A common and simple method of measuring pitch diameter is by means of the screw-thread micrometer. The micrometer is equipped with a pointed spindle and a V anvil. The angle of the point and V are made equal to the angle of the thread to be measured. The anvil is made rotatable about its axis so that in use it will conform to the helix angle. The micrometer measures from the theoretical sharp point of the thread crest to the theoretical sharp point of the root, this being equivalent to the pitch diameter. Actually, the end of the spindle and bottom of the V have clearance so that they will not rest on the bottom or top of the thread. The screw-thread micrometer is more accurate when set to a thread standard and used as a comparator. When set to zero with the faces closed, errors in measurement will occur due to the effect of the helix angle. However, for low helix angles the thread micrometer may be used to an accuracy of about 0.00025 in.

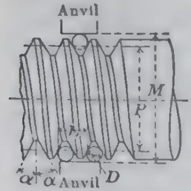

FIG. 11. Thread measurement by three-wire method.

THREE-WIRE SYSTEM. The most accurate method of measuring pitch diameter is by the three-wire system. Two wires are placed in adjacent thread spaces and held against a fixed anvil on one side of the screw; a third wire is placed between a thread space and a movable anvil on the opposite side, as shown in Fig. 11. The requisites of thread-measuring wires are extreme accuracy of size, roundness, and straightness. The diameter is held within 25 millionths of an inch of exact size. The material must be hard and wear resistant. The size of wire used in relation to pitch of the thread is such that contact will be made with the sides of the thread at the pitch diameter. This particular size is used because the resulting pitch diameter measurement is least affected by any error in the thread angle. The recommended sizes of wire for measuring 60-degree threads are given in Table 1. The pitch diameter of a thread whose sides are symmetrical about a line through the vertex perpendicular to the axis of the thread is

Table 1. Recommended Wire Sizes for Measuring 60-degree Threads

(All dimensions in inches)

Threads per in.	Wire Size	Threads per in.	Wire Size	Threads per in.	Wire Size	Threads per in.	Wire Size	Threads per in.	Wire Size	Threads per in.	Wire Size
80	0.00722	44	0.01312	27	0.02138	14	0.04124	10	0.05773	5	0.11547
72	.00802	40	.01443	24	.02406	13	.04441	9	.06415	4 1/2	.12830
64	.00902	36	.01604	20	.02887	12	.04811	8	.07217	4	.14434
56	.01031	32	.01804	18	.03208	11 1/2	.05020	7	.08248	3 1/2	.16496
48	.01203	28	.02062	16	.03608	11	.05249	6	.09623	3	.19245

$$E = M + \frac{\cot \alpha}{2n} - w(1 + \operatorname{cosec} \alpha) \tag{1}$$

For a 60-degree thread with a helix angle smaller than 6 degrees, eq. 1 becomes

$$E = M + \frac{0.86603}{n} - 3w \tag{2}$$

For a helix of 6 degrees or more, the equation becomes

$$E = M + \frac{\operatorname{cotan} \alpha}{2n} - w\left(1 + \operatorname{cosec} \alpha + \frac{T^2}{2} \cos \alpha \cot \alpha\right) \tag{3}$$

In these equations, E = pitch diameter; M = measurement over the wires; $\alpha = 1/2$ included angle of thread; n = threads per inch; w = diameter of the wires; T = tangent of helix angle = $(L/\pi)P$, where L = lead of thread.

The included angle of a thread may be determined by measuring over wires in a manner similar to the foregoing. In this case two sizes of wire are used. First, a measurement is taken over three wires having a diameter equal to or somewhat smaller than the recommended size for a given pitch. A second measurement is then made over three wires having a larger diameter, preferably near or equal to the maximum size which will fit the thread. The formula for determining the angle of thread is

$$\operatorname{cosec} \alpha = \frac{M_1 - M_2}{w_1 - w_2} - 1 \tag{4}$$

or

$$\frac{M_1 - M_2}{w_1 - w_2} = \operatorname{cosec} \alpha + 1 \tag{5}$$

where M_1 = the measurement over large wires of diameter w_1; M_2 = the measurement over small wires of diameter w_2; and $\alpha = 1/2$ included angle of thread.

Measurements over wires may be made with micrometers to an accuracy of 0.0001 in. For greater accuracies, comparators and measuring machines are used.

The accurate measurement of the lead of a screw requires more elaborate equipment than is used for pitch diameter determination. However, the chance of variation in lead of screws is not so great as in other dimensions because the accuracy of lead is determined by the more or less fixed accuracy of the machine producing it. Accurate lead measurements, therefore, are usually made only on long screws, such as machine lead screws, or on very accurate short screws such as micrometer screws and thread gages. For this purpose, lead comparators are used. This type of device measures the movement of a stylus from one thread to another in relation to either a calibrated line standard or gage blocks, and the variation from standard lead is noted by means of a microscope or a high-magnification indicator. The radius of the point of the stylus is such as to contact the thread at the pitch line. It is essential that the measurement be made along the true axis of the screw.

8. LIMIT GAGES

Limit gages, as differentiated from measuring devices and comparators, do not indicate the exact measurement of a part but only show whether or not the part is within the allowed variation. In the mass production of parts for interchangeable manufacture it is not possible to make the dimensions exact; therefore a permissible variation in the nominal size is allowed. The total variation is known as the tolerance; the limiting dimensions of the tolerance are known as the limits. In practice, the amount of tolerance prescribed for a dimension is determined by its function in an assembly. In the interests of economy, the tolerance is made as large as possible consistent with the proper functioning of the part. A limit gage is used to determine whether a part is below size, within tolerance, or oversize. In general, the gage has incorporated in it two gaging members, one set to the low limit and one set to the high limit. The gaging member that will pass over or enter the part being measured, depending on whether it is an external or an internal gage, is known as the "go" member. The member that should not pass over or enter the part is known as the "not go."

SNAP GAGES are used for gaging external dimensions. Figure 12 shows a fixed-type limit snap gage having two sets of jaws, one for the acceptable or "go" dimension, the other for the rejecting or "not go" dimension. These two sets of jaws are made to the upper and lower limits of the dimension, respectively. This type of snap gage has advantages of simplicity and cheapness. Its measuring dimensions are not easily changed by tampering. However, it is susceptible to wear, and for that reason another type is made, known as an adjustable snap gage. A commercial make of this gage is shown in Fig. 13. The anvil *A* is solid and fixed in position. Anvils *B* and *C* are adjustable, the former being set to the "go" and the latter to the "not go" dimension. Adjustment is made by differential screws as shown, gage blocks or master gages being used between the fixed and movable anvils. When properly adjusted the anvils are locked in position by clamp screws *d*. If the work being gaged is within the prescribed limits, anvil *B* will pass it, but anvil *C* will not.

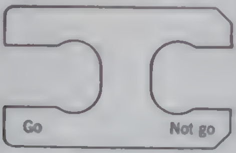

FIG. 12. Snap gage.

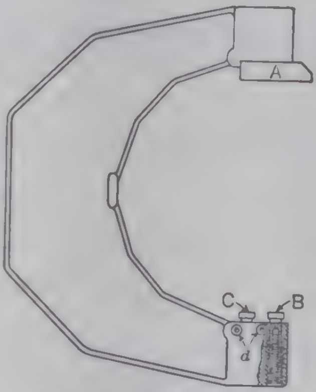

FIG. 13. Adjustable snap gage.

PLUG GAGES are cylindrical gages used for checking the size of holes. The gaging member is a simple cylinder ground and lapped to the required dimension and fastened to a hexagonal handle. When used as a limit gage, two separate cylinders are used, each finished to the limiting dimensions and fastened to the opposite ends of the handle, as in Fig. 14. The design of plug gages has been standardized by the American Gage Design Committee whose specifications have generally been followed by the gage industry. In sizes up to approximately 1.5 in. gaging members and handle are provided with tapered shanks and holes, respectively, for fastening. This type is known as the Taperlock. In sizes above 1.5 in., the member is made with a hole counterbored at each end and fastened to the handle by means of a screw. For resistance against turning of the member in the handle, three locking prongs project from the end of the handle and fit into corresponding grooves in the member. This is known as the Trilock type. The "go" and "not go" members are distinguished by the difference in length, the "go" member being long and the "not go" member short.

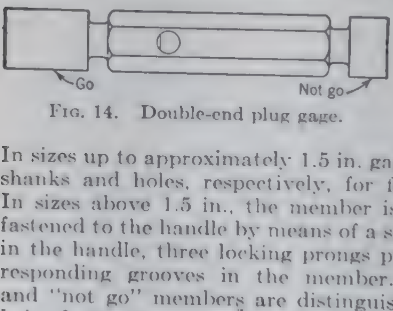

FIG. 14. Double-end plug gage.

A single-end type of limit gage is also made in which the gaging member is divided into two diameters. The diameter at the front of the member is made to the "go" dimension; the second diameter is made to the "not go" dimension. This type is known as a progressive plug gage.

RING GAGES are used for gaging diameters. The gage consists of a cylindrical member having a ground and lapped hole made to the required dimensions. Separate members are used for limit gaging, one for the "go" dimension and one for the "not go." The outside diameter of the members are knurled for easy handling, and the "not go" gage is provided with an annular groove for identification.

THREAD PLUG GAGES are used for checking internal threads. Except for the fact that the gaging members are threaded, these gages are similar in general design to plug gages described above. Thread gages are made in the single-end type to be used as reference gages or setting gages for thread ring gages, and in the double-end type for use as limit gages.

The thread angle and lead of the screw are made to the basic dimensions while the pitch diameter is made to the limiting dimension, the "go" gage being made to the lower limit of pitch diameter while the "not go" is made to the upper limit. The root of the thread is provided with suitable clearance while the crest of the thread is flatted to prescribed dimensions to avoid interference beyond normal thread contact.

THREAD-RING GAGES are used for gaging external threads. They are cylindrical members provided with very accurate central threaded holes. Since internal threads may not be measured as easily as external threads, thread-ring gages are made to the correct size by setting to a reference thread plug. The ring is provided with three equally spaced radial slots; two of them terminate in drilled holes, and the third passes entirely through the wall of the gage to allow expansion or contraction of the threaded hole. The gage is adjusted and locked to size by means of adjusting screw, locking screw, and sleeve associated with the through slot. For limit gaging, separate "go" and "not go" thread-ring gages are used.

THREAD-ROLL SNAP GAGES are combination "go" and "not go" limit gages for checking external threads rapidly.

A frame, similar to that of a plain snap gage, carries two sets of threaded rolls, each free to rotate. The first set of rolls is set to check the "go" or upper tolerance limit; the second, the "not go" or lower limit. If a threaded part passes through the first set of rolls, it is evidence that the pitch diameter is below the maximum limit. If the part does not pass the second or "not go" rolls, it is evidence that the pitch diameter is over the minimum limit, and therefore the part is correctly made within tolerance.

MEASUREMENT AND DESIGNATION OF SURFACE QUALITY

By James A. Broadston

Skilled craftsmen have worked from drawings without tolerances or finish designations for many years. As it was their practice to make and assemble all the parts of a given machine, they knew from experience which surfaces of each part required special fitting or finishing. In recent years improved manufacturing methods and mass production have made it necessary for machine operators, inspectors, and others to depend on drawings and specifications for sufficient information to permit satisfactory parts to be made, as they seldom know from their own experience the function of the part or are able to select optimum finishes. Responsibility for the control of surface quality and its proper designation on drawings now rests with the designer since he is usually the only one who knows the exact function of each surface of a part and can specify its proper finish.

9. FINISH SYMBOLS AND TERMINOLOGY

EARLY FINISH SYMBOLS. The finish symbol f was originally adopted to show both machinist and pattern maker which surfaces of a casting were to be machined. Advancing techniques soon required that a coded symbol, such as f_3, be used on drawings to indicate that, for example, a "smooth machine finish" was required. Soon these brief descriptions, based strictly on personal opinion rather than on actual measurement and therefore subject to wide variations in interpretation, were supplanted by similarly coded symbols designating that certain processes, such as *smooth grind*, be used as it was known that some processes produced smoother finishes than others. Even with this improved control, parts were often produced having unsatisfactory finishes because their acceptance was still a matter of opinion rather than measurement. Now that machine finishes whose perfection approaches that of a fine lens may be rapidly produced, within dimensional and surface-finish tolerances unbelievable a decade ago, mechanisms are designed that depend on the precise control of these factors for their successful operation. The old surface-finish designations and the loose descriptive controls they connote have therefore become inadequate.

SURFACE-ROUGHNESS MEASUREMENT AND DESIGNATION STANDARDS. In 1932 the ASA, recognizing the need for standards for the designation of surface qualities, organized a committee to study the problem under the sponsorship of the ASME and the SAE. After many years of work with industry they published, in Feb. 1947, an approved American Standard (ASA B46.1) titled Surface Roughness, Waviness and Lay.

The new standard established an approved series of values expressed in microinches (millionths of an inch, 0.000001) for designating the size of the minute geometrical irregularities existing in the surfaces of solid materials. These values, which divide the normal range of the irregularities of machined surfaces into convenient steps, serve as a measurement index to their size when used with the approved new symbol.

The standard does not specify the finishes suitable for any specific purpose or the means by which they may be produced or measured. Neither is it concerned with other surface qualities such as luster, appearance, color, hardness, microstructure, or corrosion and wear resistance, any of which may be governing considerations in specific applications.

SURFACE IRREGULARITIES COMPLEX IN CHARACTER. The precise definition and measurement of surface quality are relatively impossible because surface irregularities are usually of very complex shape and do not lend themselves to direct measurement. Surfaces produced by various methods exhibit distinct differences in character such as those that make ground, turned, milled, honed, lapped, or polished surfaces relatively easy to identify. In general, all surfaces of solid materials are composed of a series of more or less microscopic peaks and valleys. These irregularities influence such vital design factors as wear, strength, dependability, and performance of parts, and must, therefore, be considered for proper design. Although both shape and length of the irregularities may affect the overall performance of a given surface, the standard deals only with their height, width, and direction. Fortunately, surfaces normally produced by a given process have irregularities whose shapes are similar; hence it is possible through control of only their average size also to control the expected performance of a given surface within very close limits. Since this is all the designer is expected to do, adoption of the new nomenclature and the controls made possible by using measured roughness values, rather than vague descriptions based only on opinions, have made possible a great forward step in design procedures.

APPROVED SURFACE-ROUGHNESS TERMINOLOGY. Roughness refers only to relatively finely spaced surface irregularities such as those produced on machined surfaces by the cutting action of tool edges or abrasive grains. Roughness includes those minute irregularities that cover a surface completely and may be said to be characteristic of it. Measurement of roughness is the most important factor considered by the approved standard, and its designation, in most cases, permits ample control of surface quality even though the standard also provides for the designation of other values. The maximum

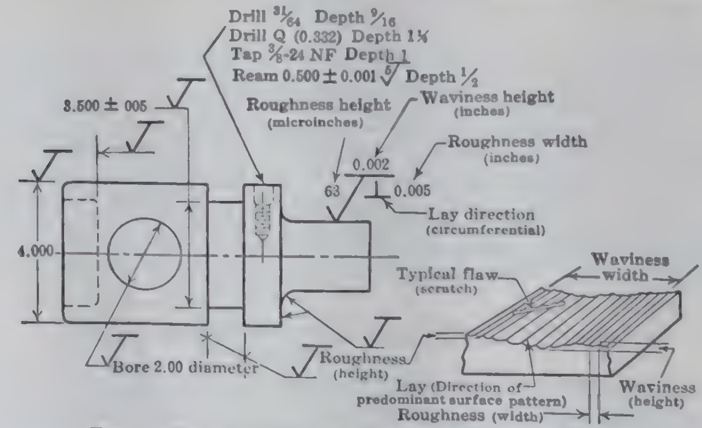

Fig. 1. Typical applications of surface roughness symbol.

allowable roughness height expressed in microinches is normally specified by the use of the approved symbol (Fig. 1) and one value from the approved standard series of Table 1.

Table 1. Standard Roughness Height Values (Microinches)

1/4	**4**	13	40	**125**	400
1/2	5	**16**	50	160	**500**
1	6	20	**63**	200	600
2	**8**	25	80	**250**	**800**
3	10	**32**	100	320	1000

In inspecting a part for conformance with a given standard roughness value, any lesser height than the one designated shall be satisfactory except that when two values are given, e.g., 32–8, they indicate maximum and minimum values. It is recommended that the *bold-faced* values be given preference because standard sets of flat surface roughness specimens for fingernail tactual comparison conforming to these roughnesses are available, making conformance with specified values easier to check.

The standard also permits the maximum allowable roughness width (repetitive units of the dominant surface pattern due to feed) to be specified in inches (adjacent to the lay symbol), as shown in Fig. 1. Roughness height specifications shall be based on irregularities having widths up to and including the maximum specified or, when not specified, up to and including the irregularities due to machine feed.

THEORY OF ROUGHNESS MEASUREMENT. Because surface irregularities are so minute and so complex it is impossible to make a simple direct measurement of roughness height. The value specified is therefore only an index value. The American Standard recognizes that it may be one of several approved indices that will serve to indicate the approximate size or magnitude of the surface irregularities.

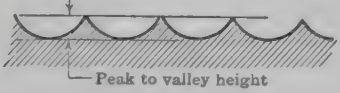

Fig. 2. Ideal regular profile of surface.

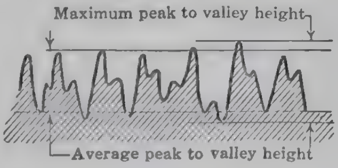

Fig. 3. Irregular profile of finished surface.

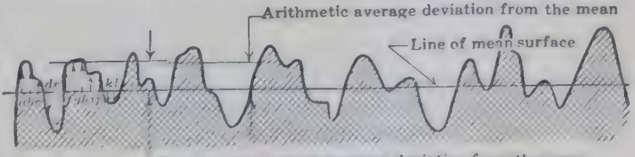
If a cross section of a given surface were highly magnified, the contour or profile of the surface irregularities might look like Fig. 2. For such a simple, regular profile, where all the peaks and valleys occur at regular elevations, the *peak-to-valley height* is simply the distance between these elevations, expressed in microinches. For a highly irregular surface profile, as shown in Fig. 3, it is customary to use one of two interpretations: (1) the *maximum peak-to-valley height*, which is the vertical distance between the elevation of the highest peak and that of the lowest valley, or (2) the *average peak-to-valley height*, which requires a personal factor of interpretation to determine the average elevation of the peaks and the average elevations of the valleys and then the vertical distance between them. These considerations make it plainly evident that these measurements depend either on human ability to find the highest peak and the lowest valley or to estimate their average heights, hence can hardly be classed as specific or duplicable measurements. Furthermore, they make no allowance for the shape of the irregularities, a vital factor in performance.

Height ratings may also be expressed as an *average deviation from the mean surface.* The mean surface is a surface located in such a way that the volume of the peaks above it is equal to the volume of the valleys below. It is the perfect surface that would result if all the peaks were leveled off and the material used to fill the valleys. The *arithmetic average* deviation of the surface of the irregularities from the mean surface is defined as the result of taking a great many uniformly spaced measurements in microinches, such as *a*, *b*, *c*, *d*, and *e*, as shown in Fig. 4, and averaging them. Should each value be squared and the square root of the average square be taken, the result represents the *root-mean-square* average. These two averages are not strictly mathematically equivalent, but general agreement exists that the difference between them is



Arithmetic average deviation from the mean
Line of mean surface
a b c
d e
f g h i j
k l
Root - mean - square average deviation from the mean

Fig. 4. Arithmetic and root-mean-square average deviations.

negligible for surface-roughness measurements. Because these averages make some allowance for the shape of the irregularities as well as their height, they have been selected as suitable indices for surface-roughness measurement.

It appears (1949) that the *arithmetic average deviation from the mean surface* should be used in preference to other values since commercial roughness-measuring instruments are calibrated for a similar value, and as future national standards may prefer it because it is simple to define and explain.

Even at best the approved standard values serve only as approximate indices to the performance of a given surface since it is easily possible that widely differing surfaces may have the same average roughness. However, if two surfaces made by the same process exhibit the same average roughness, their performance will probably be similar.

APPROVED TERMINOLOGY FOR OTHER VALUES. *Waviness* refers to those irregularities which are of greater spacing than roughness irregularities. On machined surfaces such irregularities may result from machine or work deflections or may be caused by warping as a result of the release of internal stresses, temperature effects, or other causes. Waviness heights are usually specified as maximum allowable peak-to-valley heights and with the approved standard values given in Table 2.

Table 2. Standard Waviness Height Values (Inches)

0.00002	0.00008	0.0003	0.001	0.005	0.015
0.00003	0.0001	0.0005	0.002	0.008	0.020
0.00005	0.0002	0.0008	0.003	0.010	0.025

Waviness is usually measured by using a sensitive dial indicator. Waviness widths may be specified directly in inches, but no provision for such specification is included in the approved surface-roughness symbol.

Flaws are those irregularities not characteristic of a surface that occur at one or more places at relatively infrequent intervals and are caused by lack of uniformity of the material or damage subsequent to processing. Scratches, cracks, pits, dents, and holes are typical flaws. Acceptance or rejection of a part having flaws is a matter of the inspector's judgment, as flaws are not considered in the general surface finish designation.

Lay refers to the direction of the predominant visible surface marks. Certain approved symbols are used in connection with the approved surface roughness symbol to indicate the lay direction with respect to the boundary line of the surface indicated by the symbol, i.e., = equals parallel; ⊥ equals perpendicular; × equals angular in both directions. M indicates multidirectional, C indicates approximately circular, and R indicates approximately radial relative to the center of the surface indicated by the symbol.

10. SPECIFICATION OF SURFACE QUALITY

APPLICATION OF STANDARD SURFACE-ROUGHNESS SYMBOL. The approved symbol for designating surface irregularities consists of a check mark and horizontal extension, as shown in Fig. 1. It is preferably made in the position shown. The point of the symbol may be on the line indicating the surface, on the witness line, or on an arrow pointing to the surface. In some cases it may be used in conjunction with a dimension and will then indicate surface roughness values of surfaces defined by the dimension. Values must be located exactly as shown, but it is not necessary that they all be given.

The ASA B46.1 standard requires that a general note be included in all specifications and on drawings to indicate which type of roughness height rating is intended. Many manufacturers prefer to use the NAS-30 (National Aircraft Standards) Surface Roughness Designation Standard as a drawing and specification reference, as it indicates automatically that an *average deviation from the mean* surface height rating is to be used. The NAS-30, based on the B46.1 standard, offers other distinct advantages such as provisions for notes limiting the roughnesses of surfaces not individually specified, as in Fig. 5, and for the optional use of a symbol having a flag, as shown, which is more distinctive and conspicuous, hence is less likely to be overlooked on the drawing.

All machined surfaces except as noted.

Fig. 5.

ACTUAL ROUGHNESS MEASUREMENT. The closest commercial approach to actual roughness measurement (1949) is made by tracer point instruments such as the Profilometer and Brush Surface Analyzer. These precision instruments interpret the up and down motion of a finely pointed diamond as it is drawn slowly over the irregularities of the surface whose roughness is being measured. The diamond is flexibly suspended in a suitable tracer head, and its minute irregular motion moves a coil through a magnetic field (or deforms a piezoelectric crystal), thereby generating a variable voltage which is suitably amplified and used to indicate or record the roughness of the surface. The Profilometer, which indicates average deviation from the mean surface values directly on a meter, provides an excellent method for making rapid roughness comparisons of finely finished critical surfaces. Special Profilometers and numerous accessories to improve their versatility are available. The Brush Surface Analyzer makes a greatly magnified record on a moving paper tape of the irregular motion of the diamond tracer point. This record, which depicts an approximate contour of the irregularities being traced, provides a permanent record and is not subject to the human error incident to reading a roughness meter having a rapidly oscillating needle. From such a tape peak-to-valley heights may be estimated and average roughness values determined by calculation. Surface performance may be more accurately evaluated from a knowledge of the shape of the surface irregularities, as indicated by the tape record, than by a meter reading alone. The Brush Surface Analyzer can also be equipped with a direct reading roughness meter.

All roughness-measuring instruments have inaccuracies and inherent limitations. Readings, therefore, must not always be taken at face value but should receive the benefit of intelligent interpretation based on a study of the surface configuration and performance and a knowledge of the characteristics of the instrument used.

ROUGHNESS COMPARISON. While measurement of surface roughness is a complicated procedure requiring precision instruments, the comparison of most machined surfaces with similarly finished standards of known roughness is quite simple. If the fingernail is held in scratching position and drawn lightly over a standard surface and then over the work, it is easy for even inexperienced personnel to determine which is the rougher unless their difference is so little as to be negligible. The surface quality of most machined parts can be controlled by the extensive distribution of accepted roughness standards which permit the direct comparison of prepared surfaces with the limiting values of roughness designated on the drawing by the designer. For very fine surfaces only instruments are sensitive enough for accurate comparison.

Roughness standards are commercially available in many forms for direct fingernail comparison. Some are original machined surfaces, some are plated replicas of machined surfaces, and some are molded of a hard black phenolic plastic. Since roughness comparison is essentially a tactual rather than visual procedure, the idea that a brighter surface is necessarily the smoother being false, the material of which the standard roughness specimen is made need not be the same as the material being processed, as long as the specimen is durable and corrosion resistant.

Finish comparison of finely finished surfaces can be made by using commercial devices that illuminate the surface in a manner similar to that used in the light field photomicrography of metals. These devices use a light-sensitive photoelectric cell and a meter to measure the percentage of light reflection — a very sensitive index to the surface roughness of fine surfaces. It is also possible to record and compare roughnesses by making transparent film replicas and projecting the image onto a screen. Many other methods of roughness comparison have been used that have not proved of commercial importance.

SELECTING THE PROPER SURFACE ROUGHNESS. Although handbooks now specify tolerances and dimensional clearances that are optimum for many specific applications, the state of the art (1949) is such that suitable surface roughness values based on the new standards cannot yet be specified. Designers can contribute to future progress by adopting and using the standard designations, determining the roughnesses of surfaces in their respective fields that have given satisfactory performance, and making this information available to others. A knowledge of the practical roughness range of normal machine work, together with the roughness height ratings given in Table 3, will provide a basis upon which designers can estimate surface-roughness values suitable for a given application. In general, typical surface-roughness applications are:

500√ A very rough, low-grade surface resulting from heavy cuts and coarse feeds. Suitable only for clearance surfaces that are not subject to vibration, fatigue, or stress concentration and do not make contact with other parts.

250√ This surface definitely shows tool marks from rapid feeds in producing a medium machine finish or may be produced by a very coarse surface grind, rough file, coarse disk grind, etc. It is used as a rough finish for soft alloys and for steel and hard alloys where moderate notch sensitivity exists, but a rough finish is otherwise tolerable. It is also suitable for parts where an average machine finish is acceptable and on deep bores that do not require special finishing.

125√ This is a fine machine finish resulting from high-grade machine work using high speeds and fine feeds taking light cuts with sharp cutters. It may be produced by all methods of direct machining under proper conditions, including coarse surface and cylindrical grinding, average disk grind, and ordinary hand filing. It is the coarsest finish suitable for rough bearing surfaces where loads are light and infrequent. It may also be used on moderately stressed machined parts which require moderately close fits.

63√ This is a smooth machine finish suitable for ordinary bearings and ordinary machine parts where fairly close dimensional tolerances must be held. It may be used for highly stressed parts that are not subject to severe stress reversals. It is just about as smooth a finish as can be economically produced by turning and milling without subsequent operations. On flat parts such a surface can be produced on a grinding machine.

32√ This surface corresponds to an extremely fine machine finish, a commercial carbide or diamond bore, a medium surface grind, a coarse cylindrical grind, reaming, and similar operations. In the case of turned parts, this finish may be produced by subsequent hand work with emery cloth. In using this finish and finer ones, careful consideration should be given to increased shop costs. May be used on parts subject to stress concentration and vibration. While difficult to produce on lathe, mill, or other direct machining operations, it is relatively easy to produce as centerless, cylindrical, or surface grind and is most suitable finish for hardened steel parts. May be used for bearings where motion is continuous but loads are light, provided lay is in direction of motion.

16√ Fine cylindrical grind, very smooth ream, fine surface grind, smooth emery buff, coarse hone, coarse lap, etc. Seldom used except where surface finish is of primary importance for proper functioning of part. Typical applications are for rapidly rotating shaft bearings, heavily loaded bearings, extreme tension members. It is also required for static sealing rings, bottom of sealing ring grooves, etc.

8√ Very, very fine cylindrical grind, microhone, hone, lap, buff, etc. For use only when coarser finishes are proved or known to be inadequate.

Note. 8 and finer finishes may have either a dull or bright appearance, depending on method used to produce them. Appearance of a surface shall not be considered in judging its quality. Either "feel" or roughness-measuring instruments should be used.

4√ Hone, lap, superfinish, very fine buff, or bright polish. This finish is not to be called for on drawings without special approval. It is required only in cases where packings and rings must slide across the direction of the finish grain, as in the interior honed surfaces of hydraulic struts and on buffed chrome-plated piston rods and similar operations.

STATISTICAL QUALITY CONTROL

By Charles D. Ferris

OBJECTIVES. Statistical quality control techniques are used to detect, measure, and control variability in product quality. This variability may exist in the hardness of steel gears, in the diameter of a machined shaft, in the finish of a ball bearing, in the life of a switch, to mention but a few examples. Fluctuations such as these may be responsible for reworked and scrapped parts, high inspection costs, uneven production, and, ultimately, consumer dissatisfaction if the defective work is not caught before it leaves the factory. On the other hand, the variations in the part or assembly characteristics may be well within the specification limits set by the engineer and cause no trouble in the plant or in the hands of the customer. Statistical quality control has the task of determining which is the case as economically as possible. When goods of poor quality are being produced, action must immediately be taken to determine and eliminate the cause.

The basic techniques had their beginnings over twenty years ago in the Bell Telephone Laboratories. From here their use first spread to some of the other large concerns engaged in mass production. Later the methods were adopted more generally as interest grew in academic, industrial, and military circles. Real impetus was given to their application, however, by World War II because of the urgency and magnitude of quality problems and nationwide courses offered by the Office of Production Research and Development of the War Production Board. Since the war, statistical quality control has had ever-growing acceptance in firms large and small throughout the country. At present those using its techniques are represented by the American Society for Quality Control.

In the articles that follow, the specific techniques and basic principles are considered as they apply to the fundamental phases of product quality. References to important books and articles are provided for detailed treatment.

11. INCOMING QUALITY

Maintenance of a high level of quality in incoming material is of great importance in industry. Acceptance of poor parts or subassemblies leads to difficulties in processing in the shop and assembly on the line. This, in turn, is almost certain to bring about rework and spoilage costs, production delays, and expensive inspection. The answer to these problems seems simple: subject all incoming material to a rigid incoming inspection. But such a procedure can be decidedly expensive if there are many parts. Hence, there is the practical problem of deciding when, where, and how much inspection is absolutely necessary. Several tools of statistical quality control may be employed by the incoming inspection department to strike the right balance between economy and protection. All those discussed, however, fall under the general heading of sampling inspection.

FREQUENCY DISTRIBUTION. Problem 1. Machined gears are purchased from a gear company. A critical dimension of the gear is its thickness, which must be held between 0.8270 and 0.8350 in. A lot of 2000 gears has just been received from the vendor. An inch micrometer is available for measurement. How shall this dimension be inspected?

Since it is known that successive machined gears coming off the grinding machine may vary appreciably in thickness because of wear, hardness of material, etc., we certainly want to check more than one gear. On the other hand, it does not seem reasonable to check all the gears—at least not until a reliable preliminary estimate of lot quality is obtained. To obtain such an estimate, select a sample of 25 to 50 pieces *at random*, i.e., so that each piece in the lot has an equal chance of being selected, and measure the diameters. From these data a diagram of the type shown in Fig. 1 can be constructed. Such a graph is known as a *frequency distribution.* It shows at a glance where the diameters in the sample are located. Three have a diameter between 0.8320 and 0.8329 in., seven between 0.8330 and 0.8339 in., and so on.

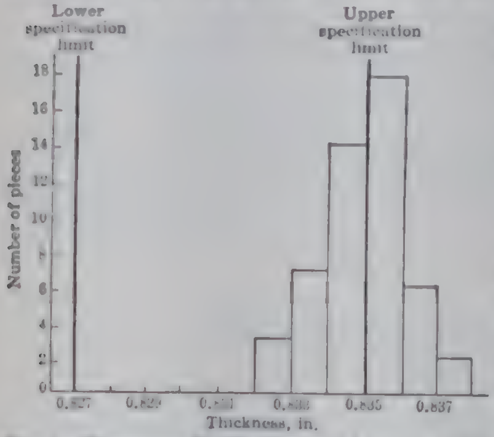

FIG. 1. Frequency distribution of thicknesses of 50 gears

This chart, then, depicts the sample thickness distribution. But theory tells us it also provides some information about the position of diameters in the remainder of the lot; exactly how much information will be discussed later. Here the frequency distribution certainly indicates that a high percentage of the pieces in the lot have thicknesses outside the upper specification limit. In other cases there might be two distinct groupings indicating two sets of manufacturing conditions. Or the distribution might have too large a spread and extend beyond both specification limits. As a working rule, visual inspection of the frequency distribution constructed from a sample of 50 will usually indicate the true situation. If the lot represented by Fig. 1 is to be used, it must obviously be sorted 100%.

For detailed information on the construction of frequency distributions and calculation of means and standard deviations, where required, consult Ref. 1.

There are some situations, mostly borderline, when it is desirable to make a more precise statement about the position of the lot distribution. In these instances select the largest value in the sample and the smallest value. The accompanying table then lists the sample size required to estimate that at least a certain percentage, b, of the lot falls between these two values while running a risk that a times in 100 actually less than $b\%$ of the lot lies between them. Such a statement does not depend on the shape of the frequency distribution of the entire lot and is based on the assumption that the lot size is very large compared to the sample size. If the latter is not the case, all risks will be less than those tabulated.

Sample Size Required

	$b = 99$	$b = 95$	$b = 90$
$a = 1$	661	130	64
$a = 5$	473	93	46
$a = 10$	388	76	37

For example, the table tells us that we can predict from 50 samples that at least 90% of the lot falls between 0.8320 and 0.8380 in. However, roughly 4% of the time we make such an estimate there will actually be less than 90% between these two end points. Observe that a sample of 661 is required to predict that at least 99% of the lot lies between the sample extremes, with a 1% chance of being wrong. For the necessary formulas, consult Refs. 2 and 3. Also of use in such problems is Ref. 4, Chapter 2.

But for the most part, visual inspection of the frequency distribution indicates the nature of incoming quality and suggests corrective action (e.g., in Fig. 1 the entire distribution should be shifted to the left). Once the reliability of incoming lots is established, the size of the sample may be substantially reduced. A sample of only 4 or 5 pieces is needed to reveal whether the lot is acceptable (see Article 12, Variable Control Charts, for details). Advantage is taken of the confidence in the supplier's performance.

ACCEPTANCE SAMPLING INSPECTION. Problem 2. Lots of a molded plastic part are being received from a vendor. A standard has been drawn up on the finish of this part. The quality of finish may vary considerably within the lot. What type of inspection should be used to protect the customer against acceptance lots of poor quality?

This problem clearly falls into a different category from Problem 1. The quality characteristic cannot be measured but only observed; the piece is either good or bad. Such inspection is known as *attribute inspection*, whereas the use of the frequency distribution is an example of *variable inspection.*

Since any per cent defective may occur in the lot, it will not do merely to inspect one or two pieces. Nor would 100% inspection seem justifiable until some preliminary investigation had proved it necessary. In other words, sampling inspection is again needed.

Before the sampling plan can be set up, the protection desired by the plan must be specified. This protection can take two forms. The first is *lot protection.* We must determine that lot per cent defective which is definitely nonacceptable (*lot tolerance per cent defective*). The second is *average outgoing quality* protection. We must set down a per cent defective which shall rarely be exceeded in the long run in outgoing lots, i.e., *average outgoing quality limit* (AOQL). Such protection assumes that all rejected lots are sorted 100%.

Finally, we must prescribe a per cent defective which is acceptable in incoming lots, i.e., *acceptable quality level* (AQL). It may be very low, say one-fourth of 1%; however, if sampling inspection is to be used, there must always be some lot per cent defective which will be accepted practically all the time by the sampling plan.

Assume that in this problem we definitely want to reject any lot in which 4% of the pieces have defective finish (the lot tolerance per cent defective). However, because of the price of the part, commercial practice, and the fact that the appearance of the molded part is not too serious a quality characteristic, we are willing to accept lots with no more than 1% (AQL) defective pieces. An attribute sampling plan can be constructed that treats lots of 1% and 4%, as specified above, practically all the time. Lots with intermediate per cent defective will be accepted varying percentages of the time, when such lots are submitted. This characteristic of a sampling plan is illustrated in Fig. 2 by a curve known as an *operating characteristic.* Such a curve traces the probability of accepting lots over the entire range of per cent defective.

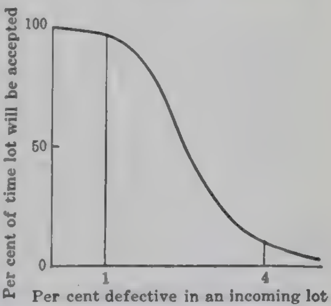

FIG. 2. Operating characteristic.

Sampling plans which provide this type of protection and their operating characteristics are contained in Ref. 5. In this reference also is the single sampling plan called for by these tables which gives protection similar to that portrayed in Fig. 2, for lot sizes greater than ten times the indicated sample size: Select a random sample of 300 pieces from the lot. If 7 or less defective pieces are found, accept the lot. Otherwise, reject.

The AOQL protection corresponding to each sampling plan and operating characteristic are listed in the tables of Ref. 5. Double and multiple sampling plans are also furnished. These sampling schemes give the same protection for less inspection but with the disadvantage of more complicated inspection procedures. For a discussion of the underlying principles of sampling inspection, see Ref. 6, Chapters 13–15.

Thus, it is possible through sampling methods to discriminate between good and bad lots, even though the type of defect does not permit precise measurement. Such a system of inspection could, of course, be applied to our first problem if we regard all gears with thicknesses outside specification limits as defective and all those inside as nondefective. Instead of using a micrometer, a snap gage of the go, not-go type could furnish necessary data.

In planning such inspection due account must always be taken of past history, confidence in the vendor, and nature of the incoming quality. If no trouble is ever experienced with a quality characteristic, inspection can certainly be slashed and, if necessary, greater risks can be taken. If the part being inspected is a molded piece, it probably will suffice to check a few pieces to make certain that the mold cavity is according to print.

ESTIMATION OF LOT PER CENT DEFECTIVE. Problem 3. In a sample of 300 pieces selected at random from a large incoming lot, 30 (10%) are found defective. What valid prediction can be made of the true percentage of defective pieces in the lot?

There are many times when we are not content merely to reject a lot as in the previous section, but wish to make an estimate of exactly how bad the lot really is. When the sample size is greater than 100, the following simple rule applies: If in a sample of n units selected at random from a large lot the fraction of defective units is designated by p, the fraction defective in the lot will lie between $p \pm 3\sqrt{p(1-p)/n}$, conservatively, 99 times in 100. In this problem $p = 0.10$, $n = 300$; hence we can predict that the fraction defective will fall between $0.10 \pm 3\sqrt{[(0.10)(0.90)]/300}$ or 0.152 and 0.048, with small risk that the true fraction defective will fall outside these values. Consult Ref. 4, Chapter 10, for an exact solution to this problem.

12. PROCESS QUALITY

Once the incoming material is accepted, two things may happen to it. First, it may be immediately used for assembly into the end product. Second, and more likely, it must undergo a certain amount of fabrication before it is ready for assembly. This may take the form of stamping, punching, plating, machining, etc. Let us look first at some applications of statistical quality control techniques in the machine shop.

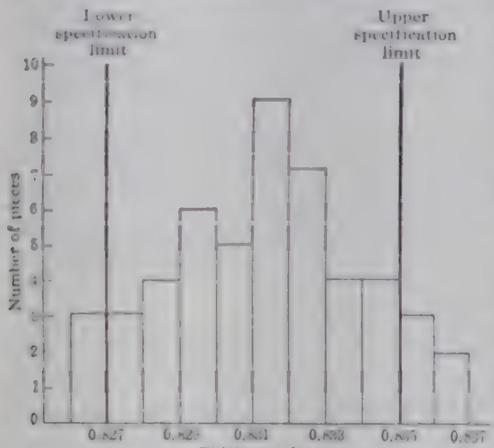

FIG. 3. Machine accuracy study.

MACHINE ACCURACY STUDY. Problem 4. The plant which had been receiving gears in an earlier example decided to do all the machining on the raw castings. What is the first step that should be taken after a machine has been set up for a production run?

Once the machine is set up, a machine accuracy study should be made. Select, say, 50 pieces at random from a short trial run, measure the thicknesses, and plot a frequency distribution as described in Article 11. By comparing the spread of the sample values with the width of the tolerance band, an idea can be obtained of how well the process will meet the specification limits during a short interval. Figure 3 is a frequency distribution of 50 measurements taken in such a study. It is clear that no matter how the process is shifted, there still will be a substantial portion of the material outside specification limits.

VARIABLE CONTROL CHARTS. Problem 5. How can the variability of gear thickness in the foregoing problem be reduced?

The secret to the solution of this problem is to determine how this process fluctuates in time. The first step is to select small samples of four or five from production at regular frequent intervals. Calculate the mean and range (largest value minus the smallest value) of each sample and plot in the order that the parts are produced. One of two situations can appear. *Situation I:* At any given moment in the grinding of the gears the thicknesses will vary about some constant thickness value as widely as the process illustrated in Fig. 3. This is an example of a state of *statistical control*—the process distribution remains constant at every point in time. *Situation II:* At any given moment in the grinding of the gears the spread is much less than that in Fig. 3, but the overall spread is increased by assignable causes which pull all the diameters being machined at that time toward either specification limit. Here we have *lack of statistical control.*

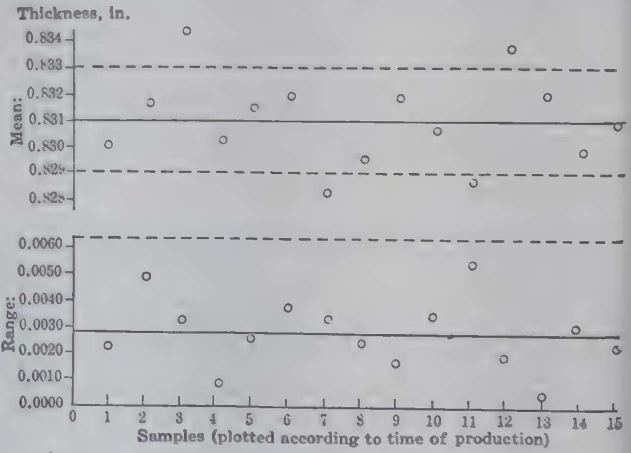

FIG. 4. Variable control chart.

A method of distinguishing between Situation I and Situation II on a practical basis was developed by Walter A. Shewhart of the Bell Telephone Laboratories more than twenty years ago and appeared in his classic treatise on statistical quality control (Ref. 7). Through simple analysis of the variability within each sample, horizontal lines are calculated and placed around the average of the small sample means. Figure 4 shows what was found when the procedure was applied to the thickness data by using samples of four.

The fact that sample means fall above the upper dotted line and below the lower dotted line indicates that one or more assignable causes of variation are present. Typical causes might be excessive hardness of the steel being used or some instability in the grinder. In this particular case the chart reveals that it is possible for the process to produce parts that meet the specification limits, provided the assignable causes can be ferreted out and eliminated. If all the sample means had fallen within the dotted limits, it would have indicated Situation I, and a fundamental methods change would be required to reduce variability. The fact that all sample ranges fall beneath the upper dotted limit signifies that the spread of thicknesses at any given moment is approximately constant.

The mean and range plots in Fig. 4 are known as *control charts;* the limits, as *control limits.* Their calculation, interpretation, and use are clearly described in Refs. 1, 6 (Chapters 4–8), and 8.

Problem 6. What should be done in the future to control the variability of gear thickness in Problem 4?

To solve, continue to select small samples from successive segments of production. Such segments should be selected on the basis that each is a potential period of change in basic manufacturing conditions. Changes in operators, steel, shifts, and tools affect the selection. These segments are known as *rational subgroups.* Plot the results on the chart, and take action whenever assignable cause of variation is indicated. This is real process control. Detailed instructions for process control procedures using variable control charts are to be found in Ref. 9 and also in Refs. 1, 6, and 8.

The techniques used in solving this problem must be flexible. If the specification limits are wide compared to the variability in thickness, and the thickness is expected to shift because of wear, *warning limits* may be set in from each specification limit (see Ref. 6, Chapter 8). The moment a mean falls outside these limits the cause must be investigated and the machine reset if excessive wear is the reason. Often a mere plot of sample points on the chart shows when the dimension is coming too close to the specification limit. Resetting will effectively prevent defective material from being produced and accepted. Regardless of the statistical technique, it is important that small samples be taken regularly from rational subgroups of production, measurements made and noted, and action be taken according to a predetermined criterion.

PER CENT DEFECTIVE CONTROL CHARTS. Problem 7. At a certain point in an assembly line, a 100% visual check is made of the finish of a critical bearing surface. Rejects have been averaging 15% of production. Production is approximately 100 pieces per hour. What can be done with these figures that will help reduce the percentage of defects?

First, calculate the fraction of rejects for each hourly, daily, or weekly interval. The unit of time depends on the least interval of time between changing factors affecting finish.

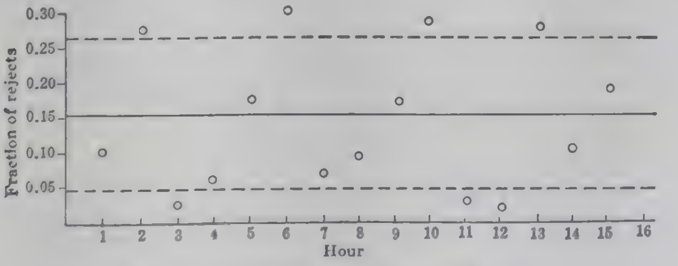

Fig. 5. Per cent defective control chart.

Since it was thought that the condition of the cutting tool from hour to hour was the responsible factor, successive hourly rejections expressed as a fraction of hourly production were computed. The points in Fig. 5 are a record of this hourly performance.

Common sense tells us that if the process were producing 15% rejections steadily, we should not necessarily expect to find 15 rejects in every subgroup of 100 inspected. Just as the per cent defective in the sample varied from that in the lot in the estimate of incoming quality in Problem 3, so we may expect these hourly percentages to fluctuate around 15%. Replacing p by 0.15, the fraction of rejects, and n by 100 in the formula cited earlier, we find that the sample percentage fluctuates between 0.04 and 0.26. These values are the *control limits* (dotted lines) on Fig. 5. The fact that hourly percentages fall above the upper control limit and below the lower control limit indicates that at times the finishing process is producing bearings that have more than 15% rejects; points below the lower limit represent a process that is producing less. Such a fact is significant because, if we can eliminate the causes of high rejections and benefit from the practice followed while producing low rejections, the average rejection level can be dropped. Actual investigation disclosed that the boring machine making the bearings was not properly adjusted during the second, tenth, and sixteenth hours, and that the cutting tool required sharpening during the sixth and thirteenth hours. After these corrections had been made it was possible to run the process "in control" at a level of 6%, further reduction being impossible until basic changes could be made in the machine.

This is an example of one of the most useful applications of the per cent defective control chart in the process. Points are plotted as the data become available, and assignable causes of variation are sought out whenever a point goes outside control limits on the chart. Of course such charts can be used on other than 100% data. They have a very important application in incoming inspection in keeping track of the quality of the vendor's product. Here the per cent defective in the sample selected from incoming lots is treated in exactly the same fashion as the 100% data above. Finally, the quality of any fabrication or assembly operation can be sampled, results recorded on an attribute basis, charts kept, and action taken. For example, the strength of a crimped connection or the presence of burrs in a reamed hole could be checked by such methods on a sampling basis. By tying down faulty performance to men, machines, materials, or methods we can put our finger on the source of the trouble and initiate corrective action.

For details on the techniques and interpretation of the attribute control chart, see Refs. 8 and 9; also Ref. 6, Chapter 10.

ACCEPTANCE SAMPLING INSPECTION. Problem 8. A washing-machine line receives 1000 gears daily from the plant machine shop. Of particular concern is the eccentricity of the gear teeth produced by six hobbing machines. What method of acceptance should be used to make certain the gears are meeting the eccentricity specification limit satisfactorily?

The vendor-customer relationship discussed in Article 11 has its parallel here inside the plant. Department A in effect buys the product of Department B. The production line accepts parts from the machine shop for purposes of assembly. In these circumstances, positive protection against acceptance of poor material is desirable. If attribute inspection is to be used, the principles discussed under Acceptance Sampling Inspection, p. 24-34, apply, with one exception. Both the cost of sorting defective material and the cost of sampling inspection are borne by the same company. Hence if the machine shop is producing gears that are 1% defective (the process average) and the line wishes lot tolerance protection at 4%, a sampling plan should be used which minimizes the total amount of inspection at the 1% level. Single and double sampling plans constructed on this principle are published in Ref. 10. The plans are in terms of AOQL and lot tolerance protection. In this instance the single sample required by the tables for a lot of 1000 pieces is 165. Accept the lot if there are 3 or less defectives in the sample; otherwise, reject.

These are not the only sampling plans that can be used in the process. When sorting costs are not a large factor or little history has been built up, do not hesitate to use sampling plans of the Navy type discussed under Problem 2.

Problem 9. Gears are coming off a boring machine and proceeding directly to the hobbing machine. How can we be sure that no more than 2% of the outgoing flow will be outside the specification limits?

Here it is impossible to accumulate a lot, and so none of the lot acceptance plans can be applied. Instead, a type of inspection known as continuous sampling must be adopted (see Ref. 11). Such a plan might provide that 10% of the pieces be checked, that sorting be instituted once a single piece is found outside specification limits, and that sorting be discontinued once 55 pieces are found free of defects. Under the usual production conditions no more than 2% of outgoing production should be defective.

To summarize, the tools of statistical quality control that can be used in the process fall into two categories. One group *samples the process* and acts to indicate the presence of assignable causes of variation. The other group *samples the product* and acts to give positive assurance that excessively defective material will not be fabricated or assembled at subsequent stages. All of them operate to reduce expensive spoilage and rework and to cut down inspection costs by sampling. Inspection has become truly preventive.

13. OUTGOING QUALITY

All the controls discussed in the previous articles operate to produce a reliable end product at minimum cost. By keeping our finger on the pulse of quality throughout the process, by trying to build quality into the product rather than cull the bad from the good at the end of the line, a healthy and economic environment for quality is created. However, there remains the necessity of checking the final unit to determine whether it conforms to all the specifications and whether the in-line controls have been properly exercised. The problem is: To what extent can sampling inspection be used at final inspection?

On some very critical performance characteristics sampling can be used only as a check on the efficiency of 100% inspection. Acceptance sampling inspection plans play a definite role in this area since inspection fatigue is a well-known phenomenon and automatic testing devices are not infallible.

In the case of less critical characteristics, acceptance sampling plans may well replace 100% inspection. Naturally the sampling plan cannot guarantee a 100% perfect product in the field, but it can assure an almost perfect product and distinguish between good and bad lots.

In addition to the usual inspection, an exhaustive quality audit and life test should be made periodically on the finished product. Appropriate action should be taken, when necessary, to change quality standards or strengthen controls.

Finally, management is interested in field results. Is poor material reaching the field? What is the expected life of a unit in the customer's hand? Statistics can help management evaluate such data properly. Action should be taken in the factory to prevent the recurrence of customer complaints.

14. QUALITY OF DESIGN

All the applications discussed so far have dealt with the treatment of manufacturing and production quality problems. Statistical techniques, however, can also assist the mechanical engineer in designing the product. Statistical principles play an important role in laying out experiments to determine the relationship among variables. Analysis of variance point out those variables that should be controlled (see Ref. 12). Proper analysis of pilot lot runs, manufactured under production conditions, permit a valid prediction of how well the product will meet specification limits once production is under way.

Problem 10 is a design problem of practical importance to the mechanical engineer.

Problem 10. A shaft will pass through a bushing in assembly. The specification limits on the shaft are 0.6008 and 0.6012 in. It is desired that the clearance between the shaft and the bushing be no less than 0.0002 in. and no more than 0.0005 in. for a satisfactory fit. Within what limits may the inside diameter of the bushing vary if this assembly specification is to be met?

The answer to this question must depend on the shape and position of the shaft and bushing diameters. It will be assumed that the diameters can be produced under a state of statistical control in the center of their respective specification bands. The diameter distribution should be bell shaped. Assembly should be completely random. The proportion of these distributions falling outside their limits should be small if the clearance specification is to be met most of the time.

To determine the bushing specification limits, B_1 and B_2, we use the formula

$$B_1 - B_2 = \sqrt{(0.6012 - 0.6008)^2 + (0.0005 - 0.0002)^2}$$

Then

$$B_1 - B_2 = \sqrt{(0.0004)^2 + (0.0003)^2} = 0.0005 \text{ in.}$$

But if the average shaft diameter is 0.6010 in. and the average clearance is 0.00035 in., the average bushing diameter is 0.6010 + 0.00035 or 0.60135 in. Hence the specification limits for the bushing are 0.60135 ± 0.00025 or 0.6016 in. and 0.6011 in.

The foregoing formula describes the manner in which variability adds up statistically, provided the assumptions hold. Although it is possible to select a bushing with a smaller diameter than the shaft, it is not at all probable. The theory can be extended to any number of pieces. See Ref. 6, Chapter 12, for a detailed discussion of the theory, with examples.

WOODWORKING

By Thomas D. Perry

1. LOGS AND LOGGING

RIVER LOGGING formerly was practiced in all forest areas where cold weather facilitated operations by freezing the ground, making roads passable, and where snow aided transportation of logs on sleds to the river side. Logs were decked high at convenient waterways, awaiting spring freshets that would float the logs to the sawmills. Winter logging still prevails in sparsely wooded areas, often with second-growth timber, but is little used in the far West and deep South.

TRACTOR LOGGING was developed because the immense size of trees on the Pacific Coast necessitated mechanical handling of logs, especially as logs up to 40- and 60-ft lengths were available and desirable for large timbers. The usual practice is to "snake" or "skid" logs by cables. A track cable is attached at one end to a high tree stump, and at the other to a steam or diesel-driven "skidder." The skidder cable is reeved through a sheave that travels on the track cable, and is attached to one end of the log. The winding drum on the skidder then lifts and drags the logs to a convenient central point, where they are loaded by derrick or small skidders on railroad cars or tractor trucks. Skidders can operate through a radius of 1000 ft.

Logging railroads usually are temporary, with little grading, and are pulled up and relocated as stumpage is exhausted. Because of excessive grades and curvature, geared locomotives are used. Corduroy roads often are required for truck and trailer operation. Trucks and trailers are of several types, trailers with regular or track-laying tractors, and trucks of the "straddle" type, where logs are hoisted and suspended between the wheels, being common.

SWAMP LOGGING often is imperative in the warmer districts where roadways do not freeze. Corduroy roads usually are necessary, with smaller mechanical equipment than on the Pacific Coast, as long logs are few in number, and most logs can be loaded by man power. In the larger swamps, like the Dismal Swamp on the Virginia-North Carolina line, canals have been dug to simplify log transportation, and many mills in such areas are supplied with logs by barge and tug. Logs also are handled by skidders to logging railroads built on crib-work or fills.

SELECTIVE LOGGING is in contrast to the earlier procedure, where timber was felled without regard to constructive forest perpetuation. This destructive logging left in its wake abandoned timber areas that were a serious fire hazard and did not develop new growth of commercial value; it wiped out industrial communities dependent on the sawmill; and it nearly obliterated all real estate values in the vicinity. Selective logging is now obligatory in removing timber from government-owned and government-controlled areas. Only merchantable trees can be removed, and the remainder are protected for future growth.

SUSTAINED YIELD, which is in accord with the modern and the economic policy, has been adopted by many large timber owners who are operating in privately held timber tracts. Not only are the trees selectively logged as they mature, but promising young growths are preserved and protected. In many cases this younger growth is supplemented by new plantings. As these protected forests develop, the smaller trees, suitable for pulp and other purposes, are removed, and thus the better trees are encouraged to grow into mature sawmill and veneer-mill material. If the brush is kept clear and fires prevented, a 20-year stand will yield pulp wood, and a 40-year growth in softwoods will begin to be available for saw logs. Hardwoods require 60 to 100 years to become desirable as lumber and veneer logs. The modern technique is to maintain and supplement young growth, to protect against fire and insect depredation, and progressively to harvest trees suitable for various purposes. It is the modern recognition of timber as a crop, in contrast to the destructive logging, which was a counterpart of the exhausted and abandoned mine.

LOG SCALES resulted from the attempts of the early timberman to state the amount of lumber that reasonably could be expected from the average log. He endeavored to eliminate the slabs, edgings and saw kerf (see p. 25-34), and to allow for the oversize of board thickness provided for shrinkage during drying. These scales were applied to the small end of the log, and the figures usually stamped thereon. The taper of the log was a factor in some scales, so that a 24-ft log does not necessarily scale twice that of a 12-ft log.

From this unscientific and rule-of-thumb beginning, numerous log scales developed, many of them of only local importance. A few which have received definite and widespread recognition are given in Table 1 (for a log 16 ft long). Other sizes, under these scales, and other scales can be found in several published woodsmen's handbooks. Figure 1 is a graphical comparison of the several log scales applied both to sawed lumber and to veneer; a log 18 in. in diameter is used as an example.

Spaulding, board feet	216	216	216	216
Spaulding, %	133	145	96	104

Log scales are used both for the purchase of logs and to estimate timber stands for valuation purposes. An experienced timber cruiser should be employed for the second function. The Spaulding and Doyle scales and their combinations are extensively used in the Midwest and the South; the Spaulding and Scribner Decimal scales are more usual on the Pacific Coast. In general, log scales favor the purchaser, rather than the seller of logs. Logs of a good grade should produce the scale footage of lumber and substantial over-runs of veneer.

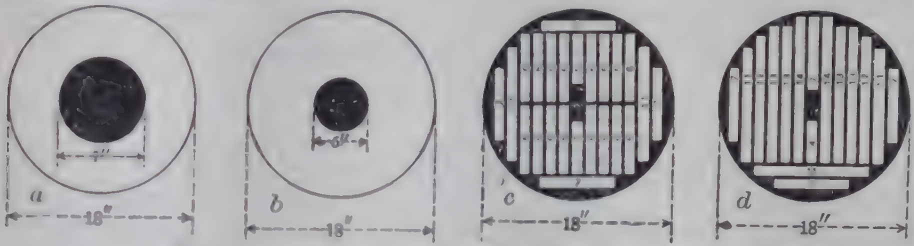

Fig. 1. Comparison of yield from 18-in. log. (See Table 2.)

2. LUMBER

SAW LOGS, suitable for conversion into lumber, usually are those between the selected peelers required for veneer and the smaller logs used for poles, posts, mine props, etc. Small blocks and down-fall are dimensioned into shingle blocks or prepared for gang sawing into lath. One-inch boards usually are cut about 1 $^1/_4$ in. thick to allow for shrinkage-thickness variations, and saw marks. Corresponding allowances are made on other thicknesses. One-inch boards should *dress clean* to $^{13}/_{16}$ in., 2-in. stock to 1 $^5/_8$ in., and 4-in. stock to 3 $^1/_2$ in.

Lumber usually is marketed as *air-dried*, containing between 15 and 25% moisture, and as *kiln-dried*, approximating 10% moisture. While considerable lumber is machined or dressed green, allowance must be made for shrinkage, which may run considerably over 10%. The shrinkage and distortion vary with the position in the log from which a piece is cut. (See Fig. 2.) Tangential shrinkage is about twice the radial shrinkage. For data on the various species of wood, see p. 5-73.

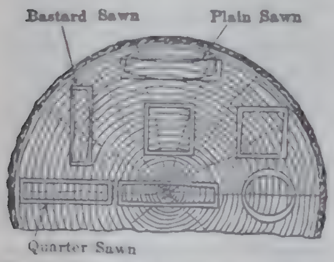

Fig. 2. Effect of direction of annual rings on shrinkage.

TYPES OF SAWING. Logs are sawed in various ways as shown in Fig. 2.

Plain-sawed or flat grain lumber customarily is cut right through the log and nominally varies from a tangent on the growth ring to a 45-degree angle.

Quarter-sawed, or vertical or edge grain, theoretically is cut on a radial line across the growth rings. In practice it may extend to 45 degrees from the radial line. In general, quarter-sawed is more carefully selected, and its angular range should be considerably less than for plain-sawed.

Bastard-sawed is a term usually applied to lumber cut between 30 and 60 degrees to the radial or tangent line. Certain species like white oak, when quarter-sawed, show distinct flake markings from the wood rays (radial), which are somewhat less conspicuous in hickory, elm, sycamore, etc.

CLASSES OF WOOD. The following terms are commonly used to describe different types of wood.

Sapwood is a name given to the several layers next to the bark, which usually are lighter in color, less dense, and more easily dried than the *heartwood* that forms the center of the tree. The life processes of growth are more active near the bark, and decrease toward the heart. Heartwood is sometimes more valuable for color, as in walnut and red gum. Its density makes it more durable for use as flooring, and, in general, its greater solid content makes it more resistant to decay than sapwood. In some trees the line of color demarcation between heart and sap is not easy to detect.

Softwood, in general, means lumber from coniferous trees, usually evergreens.

Hardwood refers to lumber from broad-leaved trees. The terms have no reference to the hardness of the wood; e.g., yellow pine, a softwood, is much harder than basswood, which technically is a hardwood.

Spring wood is that portion of the growth ring that is formed the early part of the seasonal growth. It usually is less dense than the *summer wood*, formed during the latter part of the yearly growth. Summer wood usually is mechanically stronger than spring wood. A large number of growth rings per inch is desirable from a strength standpoint.

Factory, Shop, and Yard Lumber. In general, *factory* and *shop* lumber are intended to be cut up for use in further manufacture. *Yard* lumber is of moderate sizes and intended for general building purposes. *Structural timbers* are relatively large in size, and are

selected and graded with reference to strength factors. Table 3 gives the board feet content of various sizes of dimension stock. Trade usage designates 1-in. thickness as $^4/_4$ lumber, 1 $^1/_4$-in. as $^5/_4$ lumber, etc.

AMERICAN LUMBER STANDARDS embody provisions for softwood lumber dealing with recognized classifications, nomenclature, basic grades, seasoning standards, sizes, uniform workings, description, measurement, tally, shipping provisions, grade markings, tally cards, and inspection of lumber. These standards have become well integrated in the grading rules and regulations of the leading lumber manufacturers' associations. They are widely recognized and have become well established. These standards have, on a national scale, superseded practices in various limited areas, in behalf of certain species, and in most industrial applications. They are now sponsored and maintained by the National Bureau of Standards in Washington and are kept abreast of progressive developments.

Lumber Grading Rules are promulgated by the various lumber manufacturing associations. They usually are revised from year to year, so that it is important to use the latest edition which may be obtained from the listing below. Most of the hardwood lumbermen have combined their rules in the publications of the National Hardwood Lumber Association. They also make available an inspection service, under the same rules, for all controversial points of interpretation. The softwood lumbermen are grouped in several associations, usually according to species and locality of trees. The leading lumber association is the National Lumber Manufacturers' Association at Washington, D. C., supported by and affiliated with most of the national, regional, and species associations, of which the following are the more important:

* *American Walnut Manufacturers Association*, Chicago; American walnut.
Appalachian Hardwood Manufacturers, Cincinnati; ash, basswood, beech, birch, butternut, chestnut, cherry, elm, hickory, maple, yellow poplar, red oak, white oak, walnut.
California Redwood Association, redwood.
* *Mahogany Association, Inc.*, Chicago; mahogany.
* *Maple Flooring Manufacturers Association*, Chicago; maple, birch and beech flooring.
* *National Hardwood Lumber Association*, Chicago; all hardwood species of lumber and veneer. Has grade inspection service available in all principal centers.
Northeastern Lumber Manufacturers Association, New York; northern white pine, Norway pine, eastern spruce, balsam fir, northern hardwoods.
Northern Hemlock and Hardwood Manufacturers Association, Oshkosh; hemlock, birch, maple, basswood, elm, ash, beech, tamarack, northern white pine.
Northern Pine Manufacturers Association, Minneapolis; northern white pine, Norway pine, eastern spruce, tamarack.
Red Cedar Shingle Bureau, Seattle; western red cedar.
Southern Cypress Manufacturers Association, Jacksonville; southern cypress.
Southern Hardwood Producers, Inc., Memphis; ash, basswood, beech, yellow cypress, cottonwood, elm, black gum, red gum, hackberry, hickory, red maple, magnolia, white oak, red oak, poplar, pecan, persimmon, sycamore, tupelo, willow.
Southern Pine Association, New Orleans; longleaf and shortleaf pine.
West Coast Lumberman's Association, Seattle; Douglas fir, west coast hemlock, Sitka spruce, western red cedar, Port Orford cedar.
Western Pine Association, Portland; ponderosa pine, Idaho white pine, sugar pine, larch, Douglas fir, white fir, Englemann spruce, western red cedar, incense cedar.

3. VENEER OR THIN LUMBER

VENEERS are thin sheets of wood, which are, excepting a minor amount of sawed veneer, knife-cut by various processes. (See below.) There is no saw kerf waste in knife cutting, rotary veneer being cut continuously from the log (see Fig. 3), and sheets of sliced veneer being cut from flitches, i.e., log sections, in widths as they come, without edging (see Fig. 5). Hence the conversion of logs into veneer utilizes much more of the log than does sawing into lumber. (See Fig. 1 and Table 2.) The assembly of veneers into plywood distributes wood strength more effectively than does solid lumber. Hence thinner veneers (in plywood form) provide equivalent strength factors as compared with thicker solid lumber. The four principal types of veneer, distinguished by different cutting processes are rotary veneer, sliced veneer, half-round veneer, and sawed veneer.

Rotary veneer, cut on lathes, accounts for approximately 90% of all veneer. As very little face veneer is made by this process, with such exceptions as bird's-eye and quilted maple, rotary-cut veneer usually is called commercial veneer. It is used for cross bands, cores, and faces where strength is more important than appearance. Rotary veneer may be as thin as 0.01 in. It is difficult to cut thicker than $^1/_4$ in., although $^5/_{16}$-in. and $^3/_8$-veneer sometimes is cut from softer woods like basswood and poplar. Few veneer lathes are over 8 ft long (some are 10 ft) because of the difficulty of cutting accurately across the unsupported distance between lathe centers. Figure 3 shows rotary cutting, the veneer being unrolled over a knife, much as paper is unrolled. The convex side is the *tight* side and often is marked with crayon during lathe cutting.

---

* National in scope, usually including Canada.

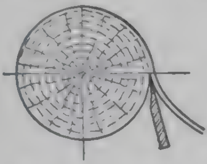

Fig. 3. Rotary veneer cut on a lathe.

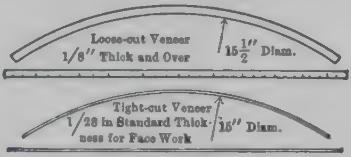

Fig. 4. Tight and loose cutting of veneer.

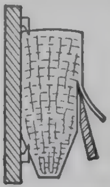

Fig. 5. Sliced veneer cut quartered from a segment flitch.

Figure 4 shows tight- and loose-cut veneer. The cutting checks on the loose side may result from inadequate pressure. They cannot be eliminated entirely and frequently cause the veneer to flatten better. In some stock, however, they sometimes are objectionable. The process of flattening veneer from its original curved shape need not result in checks or splits on the concave side in veneer under $^1/_8$ in. thick. Proper pressure produces tight-cut veneer and avoids cutting checks. Both sides of the veneer then can be used, as in matched faces. See Fig. 20 for book matching.

Sliced Veneer. Figure 5 shows the method customarily used in cutting valuable face veneers. Much of the most attractive face figure, such as mahogany and walnut, is developed from slicing on the "quarter" as shown. Adjacent sheets can be "book-matched" by opening a flitch like the pages of a book, to produce balanced symmetrical figure. Sliced veneer does not have the cutting checks characteristic of rotary veneer. It may be as thin as $^1/_{100}$ in. but seldom can be thicker than $^1/_8$ in. It is regularly cut up to 16 ft long.

Half-round veneer cutting is an intermediate process between rotary and sliced. Two distinct types are cut, *regular and back cut.* (See Fig. 6.) Cutting is done in a lathe in which the log or flitch is swung eccentrically between centers on a *stay log,* the radius of knife cut being much greater than in ordinary rotary cutting.

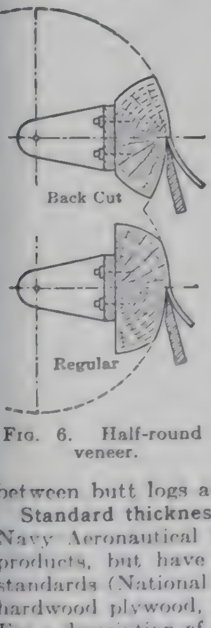

Fig. 6. Half-round veneer.

Skillful cutting of these three types of veneer depends principally on proper adjustment and manipulation of the relations between the knife and the pressure bar. (See Fig. 7.)

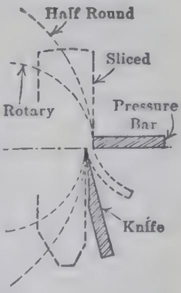

Fig. 7. Positions of pressure bar and knife in veneer cutting.

Sawed Veneer. A few face veneers are sawed on a large diameter segment saw, particularly to reveal the flake of woods like quartered white oak. The minimum thickness for sawed veneer is $^1/_{20}$ in., when the saw kerf waste is equal to the veneer; the maximum may be $^3/_8$ in. or more.

Weights of Veneer. Weights of single-ply veneer, representing the more common species and the thicknesses usually employed in veneer and plywood work, are given in Table 4. Since wood, within a species, varies considerably as between heartwood and sapwood, between river bottom and mountain growth, and between butt logs and upper logs, reasonable tolerances must be observed.

Standard thicknesses for veneer and cutting tolerances have been established (Army Navy Aeronautical Specifications AN-P-69a, February 1946) for government aircraft products, but have not been adopted, generally, for commercial work. Commercial standards (National Bureau of Standards) have been established for both softwood and hardwood plywood, including the suitable types and grades of veneer to be employed. For a description of grade rules and face figure nomenclature, consult the publications of the veneer associations, the more prominent of which are American Walnut Manufacturers Association, Chicago; Mahogany Association, Chicago, National Hardwood Lumber

Association, Chicago; Pacific Veneer Package Association, Tacoma, Wash.; Rotary Cut Lumber Association, New Orleans; Veneer Association, Chicago; Veneer Package Association, Washington.

Table 4. Weights of Veneer

In ounces per square foot of single-ply, oven-dry.

The weight of wood varies within a species so that although the table gives average weights, substantial variations may sometimes be found.

Species	S.G. (1)	M.C. (2)	Thickness in Inches

4. SAWMILLS

Sawmills are either permanent or portable. The former are used to saw the timber from large tracts, where the life of the operation will be 10 years or more. The latter are used in small tracts. They are so constructed that they can be moved easily from place to place, and are driven by steam, gasoline, or diesel engine. Both types of mill use either band saws or circular saws. The former are higher in first cost, but the waste in saw kerf is much less.

ARRANGEMENT OF SAWMILLS. Sawmills may be either single or double, i.e., the equipment of a double mill is largely in duplicate, and arranged symmetrically on either side of the center line of the mill. Modern practice tends to the use of band saws;

a mill with one such saw is known as a *single-band mill;* one with two saws is a *double-band mill.*

A typical double-band mill can be designed to cut 100,000 board feet of lumber per day, with a steam gang saw for sawing balks of timber into boards. In many mills a horizontal or vertical band resaw replaces the gang saw. The machinery floor of the mill is elevated 15 to 20 ft above ground level. Line shafts or other drives are located below the floor.

Logs are drawn from the long pond or other storage and elevated to the mill floor by a *log slip,* i.e., an inclined chain conveyor, which may be single or in duplicate. At the head of the log slip, the logs are cut into convenient lengths by a deck saw. This is a horizontal or vertical swing saw, 6 ft or more in diameter, belt or motor driven, moved to and fed through the log by steam or air cylinders. Steam-actuated *kickers,* i.e., steam cylinders whose piston rods terminate in large forked ends, kick the sawed logs from the log slip to the *log deck,* whence they are transferred to the saw carriages. Steam *niggers* transfer the logs from the log deck to the saw carriages, and also turn over the partially sawed logs to present new surfaces to the saw.

The carriages carry the logs back and forth past the band saws. An operator riding on the carriage, by means of appropriate *set works,* advances the log toward the saw after each cut to obtain the desired thickness of lumber.

The lumber as it comes from the saw is moved by the live roll conveyors and chain transfers to any one of a series of operations. Lumber sawed to correct widths moves on the first roller conveyor to the transfer chain to the trimming saws, which cut it to proper length. Lumber of irregular width is moved by chain transfers to the double edgers which cut it to width, whence it passes to the trimming saws. Large balks of timber are moved by the chain transfers to pass through the steam gang saw which saws the balk into planks; the planks then move to the trimming saws.

If a band resaw is used instead of a gang saw, the balks travel on the first live roll bed to the far end of the mill. A chain transfer then moves them to the middle live roll bed, which returns them in the reverse direction to the band resaw, where they are sawed into boards. The chain transfer moves these boards again to the first live roll bed, which delivers them to the trimming saw.

Refuse from the various operations is disposed of in several ways. Sawdust from each operation drops into a conveyor which moves it either to a fuel storage or direct to the boiler plant. Trimmings, edgings, and other pieces that are large enough are placed on conveyors to transport them to the lath and shingle mills for conversion into marketable product. Other waste is diverted to the slasher which saws it into pieces short enough to be used as fuel.

Finished lumber from the trimming saws is placed on the sorting chain. This is a two- or three-strand chain conveyor 400 to 800 ft long, on which the lumber is graded and sorted into convenient stacks for transfer to the lumber yard or dry kilns.

SAWMILL MACHINERY. Band Mills. A band mill comprises a heavy cast-iron frame and column carrying an upper and lower band wheel on which runs a band saw. The shaft and bearings of the upper wheel are movable, vertically, for the purpose of putting proper tension on the saw. The mill is driven by a belt pulley on the shaft of the lower wheel. Band mills are commonly made with band wheels 6 to 10 ft in diameter, and the diameter of the wheel designates the size of the mill. The saws range in dimensions from 10 in. wide, No. 16 gage, on 6-ft mills, up to 18 in., No. 12 gage, on 10-ft mills.

Saw carriages are massive timber frames carried on 8 to 12 wheels, riding on T rails. The headblocks, which carry movable knees, are mounted on the carriage. The knees each have two sets of dogs with teeth pointing upward and downward, respectively. These dogs grip the round log or *balk* of partially sawed timber, and hold it firmly against the knee while the carriage moves past the saw. After each saw cut, the log or balk is advanced the desired amount for the next cut, by means of *set works* which move the knees forward on the carriage. Set works usually are designed to advance the knees by multiples of $^1/_{32}$ in. The operator rides on the carriage and manipulates the set works in accordance with directions from the sawyer.

Two general methods are in use for moving the carriage past the saw: (1) *Steam* or "*shot-gun*" feed, consisting of a steam cylinder, in line with the carriage, and of a stroke equal to the travel of the carriage. (2) *Twin-engine* feed, in which a pair of opposed engines operate an endless cable from a drum to the carriage.

Gang saws are reciprocating saws, mounted in gangs, to saw large balks into a number of planks in one operation. Twenty-five to 54 saws are mounted parallel to each other, the requisite distance apart to saw planks of the desired thickness, and either belt or engine driven. The saws are carried in a steel sash, which is reciprocated vertically by a pitman driven by a crankshaft below the sash. Work is fed to the saws by fluted feed rolls, driven by a friction feed, whose speed can be varied by the operator. Pressure rolls actuated by steam cylinders hold the work firmly in place during sawing.

Band resaws are of both horizontal and vertical types. The vertical type is, in general, similar to the band mill, with adjustable feed rolls on either side to provide for resawing various thicknesses of stock. The horizontal band resaw has a horizontal blade, the upper run of the saw operating across one or more adjustable feed tables, which control the thickness. Pressure rolls, independently adjustable on each table, permit the simultaneous sawing of different thicknesses.

Edgers. Double edgers consist of a series of circular saws that can be moved in an axial direction on their arbor. The position of the saws is adjusted by the operator to the desired width of stock. Double edgers are used to remove rough or wany edges from slabs to form a single plank, or to saw a wide slab into narrower planks. Saws range from 20 to 24 in. in diameter, and usually are direct motor driven, although belt drive is also used. Edgers are provided with pressure and feed rolls both before and behind the saws.

Slashers. A slasher consists of a series of circular saws spaced at equal intervals on an arbor above the feed chains conveying the waste material from the live rolls to the slasher saws. Saws are set for cutting suitable lengths for lath, shingles, or waste, and a conveyor transfers the sawed slashing to its proper destination.

Trimming Saws. Trimming saws comprise a series of swing saws suspended over transfer chains, somewhat similar to those used at the slasher. The saws are placed so that any two of them will saw boards to commercial lengths, as may be determined by the operator for each successive board or plank.

Niggers and log loaders are mechanical devices, located below the log deck, for turning or moving the logs and balks toward or against the knees of the saw carriage.

Manufacturers. Sawmill machinery is built by Allis-Chalmers Co., Milwaukee, Wis.; American Saw Mill Machinery Co., Hackettstown, N. J.; F. L. Estes Saw and Machinery Co., Nashville, Tenn.; Filer and Stowell Co., Milwaukee, Wis.; Gainesville Iron Works, Gainesville, Ga.; Standard Saw Mill Machinery Co., Erie, Pa.; Taylor Iron Works and Supply Co., Macon, Ga.; Wheland Co., Chattanooga, Tenn.; J. A. Vance Co., Winston-Salem, N. C.

SAWMILL DRIVES. Sawmills are, in general, driven either from one or more line shafts extending the length of the mill, underneath the machinery floor, or by electric motors driving machines individually or in groups. In line-shaft drives, the main shaft is belted to a steam engine or electric motor. Sometimes a rope drive is used to transmit power from the engine. Where the driven machine is at an angle to the line shaft, mule pulley drives (see p. 15-52) or large bevel gears with wood teeth or bevel friction gears (see p. 15-83) are used to change the direction of the power supply. Final drive to the individual machines usually is by belt. Line-shaft speeds are from 150 to 250 rpm. Line shafts usually are carried in rigid post bearings. In the more modern mills, all bearings are force lubricated from a central point by an oil pump, reservoir, and oil filter.

Steam engines used for line-shaft drive are of various types. Steam economy seldom is given consideration in sawmill practice, as wood waste is used for fuel, and usually there is more available than can be burned for steam making. However, it should be remembered that wasteful engines require a larger boiler plant, with consequently greater first cost and overhead and operating charges. Many mill engines exhaust direct to atmosphere and use live steam in the dry kilns, but this practice also requires greater investment in boilers than where exhaust steam is used in the kilns. A few mills which have ample water available operate condensing, and use live steam in the kilns.

Power Requirements. The power required to drive a sawmill with line shafts varies widely with the type of equipment, the character of maintenance, and other factors. A mill of the type described usually has installed engine capacity of about 1000 hp. Indicator cards from engines driving several mills of this type showed a maximum demand of 850 to 900 hp.

Where the mill is to be motor driven, manufacturers of equipment will recommend the size of the motors to be installed. For line-shaft drive, the power must be estimated from previous performances of similar mills. The following figures were used in estimating the requirements of a double-band mill described above. They are given as a general guide only, and should be checked against local conditions. The figures are indicated horsepower except as otherwise stated. Deck saw, 30 hp; 8-ft band saw, 225 hp; 48-in. gang saw, 225 hp; 72-in. double edger, 150 hp; slasher, 50 hp; trimming saw, 40 hp; chain transfer to gang saw, 5 hp; chain transfer to trimming saw, 15 hp; nigger, 40 boiler hp; shot-gun feed for carriage, 14 in., 120 boiler hp, 12 in., 80 boiler hp. The load factor generally is taken as 80%.

5. VENEER LATHES AND SLICERS

The accuracy requirements for veneer cutting demand more careful log preparation than for lumber sawing. Logs for rotary cutting are cut to length on a *drag saw*, blade, circular, or band. The short lengths, or *bolts*, are sorted by length and species, and placed in vats for cooking or steaming. To produce sliced, half-round, and sawed veneer, logs are sawed into flitches, partly to obtain face figure and partly to facilitate clamping on the machine bed. Every veneer mill producing these latter types requires a small band (band-saw) mill both for flitching and to salvage lumber from unsuitable and defective logs that will not make veneer. Flitching technique varies widely according to log shape and veneer character. Figure 8 shows a suitable method of flitching oak logs, 24 to 30 in. in diameter, for quartering. In crotches, stumps, and burls, only experience and judgment can solve the widely varying individual problems of flitching. Flitches, except for the sawed veneer, go to the vats.

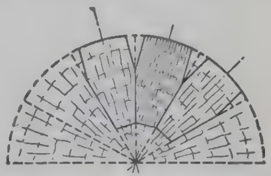

Fig. 8. Flitching for quarter-sawed veneer.

COOKING OR STEAMING. A few species of veneer woods, as basswood, poplar, and similar woods, are best cut "cold," without cooking. All logs are improved for veneer cutting by soaking in a log pond. The best authorities advocate cooking logs in hot water. Temperature and duration of cooking vary widely with the species, size, texture, and freshness from the woods. A minimum is 4 to 6 hr at 200 F up for coniferous woods, extending to 15 to 20 hr at 150 to 175 F for hardwoods. Flitches of fragile figure are best soaked for longer periods at 100 to 125 F. Too much cooking produces "fuzzy" veneer. Logs are barked before mounting and should be not more than 30 min from vat to machine. Some operators prefer steaming, a shorter and more intense process that is too harsh for fragile woods and does not properly penetrate others.

A cooking vat should be built of concrete liberally reinforced, especially at corners, to withstand severe temperature strains. It usually is made about 6 ft deep by 10 ft wide; the length is varied to suit capacity. Covers, preferably of steel plates with central rings, are handled by the crane used for bolts and flitches.

VENEER LATHES. Figure 3 shows the principle of operation of a rotary veneer lathe. Details of the cutting mechanism are shown in Fig. 9. Logs are mounted in the lathe from the back by crane. Standard operating speed, traditionally, is 25 to 30 rpm to accommodate 30-in. logs. This is slow for small logs. Spindle chucks or centers usually are 5 or 6 in. in diameter for 60- to 100-in. bolts, leaving a 7-in. core that is defective in many species but sometimes can be cut into crating. Lathes usually are equipped with 50- to 75-hp motors for 60- to 100-in. lengths and logs up to 30-in. in diameter. For larger logs, as on the Pacific Coast, power demand is greater. An efficient setup would be mechanical speed control permitting speeds to be changed without stopping lathes, giving 48, 36, 30, and 24 rpm, and permitting linear veneer delivery speeds of 100 (for thick veneer) to 200 ft per min. Electrical speed controls are to be avoided, as motors incline to race under wide load variations, caused by thick and thin cuts, and large and small logs. Table 5 shows the resulting delivery speeds in such a setup. Rotary box veneer often is cut at 60 rpm, but quality requirements are low. Figure 10 shows a typical lathe layout, with delivery tables, clipper, and crew location. In species with sound cores, as birch, a supplementary high-speed (50 rpm) lathe sometimes is provided with 3-in. chucks to cut $^1/_{20}$-in. veneer from 7- and 8-in. cores, 42 in. long or less.

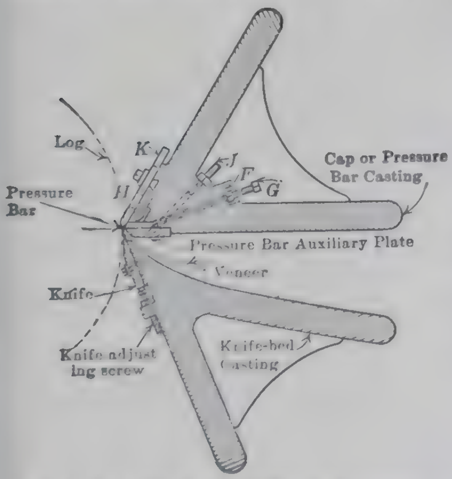

Fig. 9. Details of veneer lathe cutting mechanism.

The veneer comes off the lathe in long ribbons and frequently goes direct to the clipper on a conveyor, where it is dimensioned for width, singly or in piles. In most cases either the clipper or the lathe is slowed down by this direct connection, or the quality of the veneer is sacrificed by rapid clipping in piles. An alternate procedure, which has been

Table 5. Actual Veneer Delivery Speeds, Feet per Minute

used in Europe for some time and has been adopted by several American veneer mills, is to reel the green veneer on drums direct from the lathe, store the drums on racks under a conveyor, and transfer them to the clipper table at a rate that permits careful quality cutting. This method conserves quality and increases yield in the better grades of veneer.

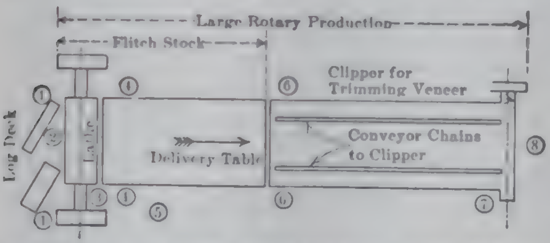

FIG. 10. Standard veneer layout and crew. Standard crew is: (1) 2 log peelers, (2) 1 log hanger, (3) 1 lathe operator, (4) 2 off bearers or breakers, (5) 1 waste collector, (6) 2 off bearers for large production, (7) 1 clipper operator, (8) 1 clipper off bearer.

VENEER SLICERS. Figure 5 shows the operating principle of a veneer slicer. Flitches are mounted on the table or bed by dogs, the table moving up and down on angling ways to produce a shear cut. The typical cutting stroke is about 3 ft. The draw or lateral movement of the knife is about 1 1/2 ft. Cutting is done on the down stroke, and the log is fed forward on the return stroke of the knife. Horizontal slicers are used more in Europe than in the United States and afford greater latitude in range of angle cuts, often desirable in highly figured flitches. Veneer delivery equipment for slicers is simpler than for lathes. Flitch-cut veneer always is kept in sequence to permit matching.

HALF-ROUND VENEER is an intermediate method between rotary and sliced veneer. (See Fig. 6.) The log is flitched or sawed, as in slicing, and cooked. It is cut on a lathe provided with a *stay-log* swung from the lathe centers, with radial adjustment and provided with a table or bed to which flitches are clamped with bolts. Half-round veneer has more regular grain than rotary veneer.

CUTTING MECHANISM (Fig. 9) is essentially the same in both lathes and slicer. Its proper adjustment and manipulation are the critical factors in good veneer cutting. The feed mechanism in both lathes and slicers is mounted on two screws, moving the lathe carriage with the cutting mechanism into the log or flitch a distance equal to the veneer thickness at each revolution or stroke.

Rotary veneers usually are cut to widths providing whole, half, third, and quarter parts of the desired sizes. Flitch veneers are kept together after numbering and taking several sample swatches from top, center, and bottom of each flitch.

VENEER DRYERS comprise rollers, traveling plates, or mesh belts, on which veneer passes progressively through drying chambers. Controlled temperature and humidity establish the necessary moisture deficit to dry various thicknesses at a single pass, the speed for thicker veneers being reduced. Veneer usually is dried to 10% moisture content. It must be dried within a few hours after cutting to prevent discoloration.

Manufacturers. Veneer machinery is built by Merritt Engineering and Sales Co., Lockport, N. Y.; Capitol Machine Co., Indianapolis, Ind.; Coe Manufacturing Co., Painesville, Ohio; Proctor and Schwartz Co., Philadelphia, Pa.

6. LUMBER DRY KILNS

EQUILIBRIUM MOISTURE CONTENT. Wood products, in service and storage, should have, as nearly as possible, an equilibrium moisture content in the wood parts to keep at a minimum dimensional changes (shrinkage and swelling) due to moisture changes. Under ordinary room conditions this is about 6 to 8% moisture content; in normal outdoor weather 10 to 15%. Lumber is stronger and stiffer when dry than when wet. Dry wood (to the extent mentioned above) will retain paint and finishes, whereas wet lumber will not hold surface coatings. Table 6 gives conditions for maintaining moisture content equilibrium in lumber. Correct atmospheric conditions are particularly important in raw lumber storage rooms.

Table 6. Variation of Equilibrium Moisture Content of Wood

LUMBER DRY KILNS are of two principal types. In the single-charge (*box* or *compartment*) kiln, the lumber charge remains stationary during the drying cycle; in the *progressive* kiln the lumber moves in the kiln through the various stages in the drying cycle, from the initial low-temperature-high-humidity condition to the final high-temperature-low-humidity stage. Figure 11 compares the two types.

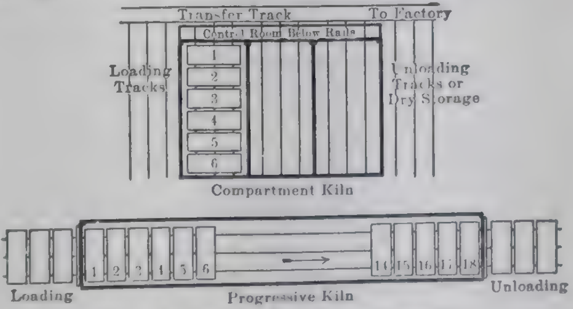

FIG. 11. Dry kilns with equal capacity.

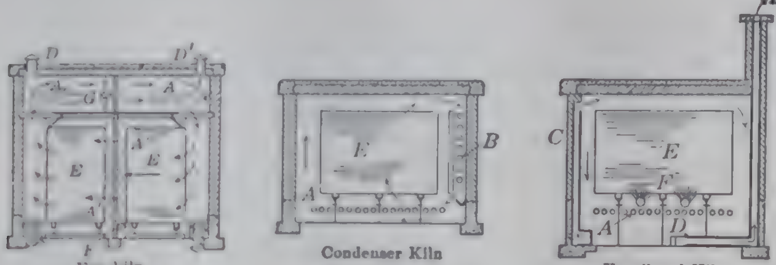
The method of piling lumber in the dry kilns may be *crosswise*, as shown in Fig. 11, in which the length of the boards is at right angles to its movement into, through and out of the kiln; or *endwise*, in which the boards are parallel to the movement of the lumber, as shown in the left-hand sketch of Fig. 12. Either method is suitable for ventilated or condenser kilns, but the endwise method is preferred for fan kilns.

In ventilated or condenser kilns (Fig. 12) the boards in each layer are placed 2 or 3 in. apart, since the air moves both horizontally and vertically, so that only 60 to 75% of the space in each layer can be utilized. In fan kilns (Fig. 12) the boards are laid close together edgewise, since the air travels only horizontally. Hence the kiln capacity is considerably greater. In all cases the intervening stickers, between the layers of boards, should be of uniform height, and laid in accurate vertical alignment, so that all boards will be held straight and true during the drying process.



Fan kiln

Condenser Kiln

Ventilated Kiln

FIG. 12. Types of kilns. *A*, *A′*, heating unit. *B*, condensing unit. *C*, fresh air inlet. *D*, *D′*, used air outlets. *E*, lumber charge. *F*, humidifying unit. *G*, reversible fans.

DRYING TECHNIQUE is of three principal forms, as shown in Fig. 12. (1) Forced circulation, or *fan kilns*, in which the air is forced mechanically through between the layers of lumber, and the fan circulation reverses at stated intervals to equalize the drying effect. Supplementary or booster heating coils are frequently placed between the loads of lumber as shown. (2) *Condenser kilns*, where moisture-laden air passes over condensing coils (usually circulating cold water pipes), is reheated, and again passes through the lumber, and so on for a series of cycles. (3) Natural circulation, or *ventilated kilns*, where the air movement is accomplished by gravity. Heating pipes are often installed in the outlet ducts to accelerate the ventilation. In this case adequate air inlets and outlets are of prime importance.

The present tendency is toward fan kilns, since their capacity is greater by eliminating the spaces between the boards; and their steam consumption is less, due to the recirculating feature that conserves the atmospheric heat within the kiln. Condenser kilns are seldom used, and many ventilated kilns are being replaced with fan types.

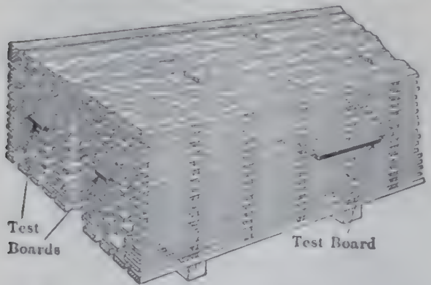


FIG. 13. Kiln stack, showing locations of test boards.

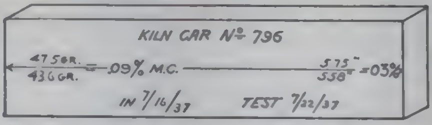

FIG. 15. Method of marking test samples.

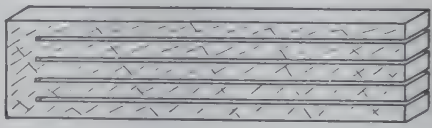

FIG. 16. Test sample for case-hardening.

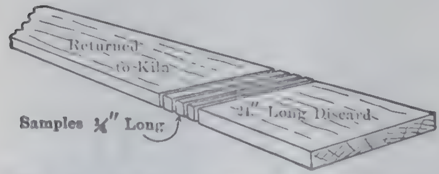

FIG. 14. Location of sample in test boards.

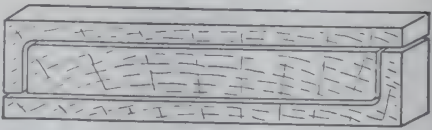

FIG. 17. Test sample to determine dryness between center and outside.

Most kilns have steam or water sprays to maintain the humidity. Temperature and humidity controls, usually with recording attachments, are essential to maintain schedule requirements. In kiln-drying programs, *humidity* refers to air conditions, and *moisture content* means the moisture contained in the lumber. The latter is computed by weight, weight of dry wood being divided into the weight of moisture removed:

$$MC = \frac{W_i - W_d}{W_d} \times 100$$

where MC = moisture content, per cent; W_i = initial weight; and W_d = oven-dry weight.

In general, temperatures of 200 F can be used safely on 1-in. (4/4) softwoods; for hardwoods the temperature range is 150 to 160 F. With thicker and greener lumber, these temperatures must be reduced.

TIME REQUIRED FOR KILN DRYING of pine and similar softwoods usually is 3 to 5 days, from the original tree condition of greenness to about 10% moisture content, usually considered shipping dry. Hardwoods require varying times, according to thickness, original and desired moisture content, and types of kilns available. A general survey of these drying times is given for internal fan kilns in Table 7.

Willow	3–4	5–6	6–7	10–12

It is highly important that lumber be uniformly kiln dried to the required moisture content, and be maintained at that point during the entire product manufacturing procedure. In fact, most kiln authorities advocate kiln drying slightly below required conditions, and allowing reabsorption to equilibrium point in dry storage.

Tests for moisture content usually are made by weighing samples. When tests are required, samples are cut from test boards whose locations in the kiln load are shown in Fig. 13. The locations of the test samples in the test boards are shown in Fig. 14. The board ends, which probably are overdried, are discarded. Figure 15 shows the best procedure for marking weighed samples for filing, the figures on the left being moisture content and those on the right shrinkage. In both cases the upper figures are values immediately after cutting test samples; the lower figures are values after oven drying to minimum obtainable conditions, i.e., bone dry. Figure 16 illustrates a test sample prepared to show case hardening. If the prongs flare out, the sample is case hardened but dry; if they pinch, it was case hardened before drying, and the stresses were not relieved during drying. A further test for exterior and interior moisture content is shown in Fig. 17. The test sample is band sawed, and outer and inner portions weighed before and after oven drying to determine the moisture content of each. A normal moisture content gradient usually will show an excess of 1 to 2% for the inner section.

Kiln Accessories. For kilns and adjoining storage tracks, 35-lb rail generally is used, supported at 6-ft intervals. Kiln bunks or trucks should have roller bearings, frequently lubricated because of the heat. Kiln transfer cars will facilitate lumber distribution from railroad unloading siding direct to kilns, and from kilns to dry storage and cutting rooms. They are usually about 12 in. high, rail top to rail top, and preferably are motor driven. Lumber lifts elevated by motor-driven revolving screws, in a pit below, are essential both for loading and unloading kiln cars, as well as for keeping the top of the lumber load at convenient height for serving rough planers or cut-off saws. Some mills use locomotive cranes with 40-ft booms to transfer lumber in packets to and from kilns and lumber piles in the yard.

Manufacturers. Lumber dry kilns are supplied by Standard Dry Kiln Co., Indianapolis, Ind., Moore Dry Kiln Co., Jacksonville, Fla., and Portland, Ore.

7. MACHINE OPERATIONS AND LAYOUTS

In wood products factories, machine, and department arrangement are substantially similar in major items, with considerable divergence in minor details, because of difference in character of products and degree of premanufacture in raw materials. A typical example of standard procedure is given in Table 8.

8. PLYWOOD AND GLUING

FLAT PLYWOOD. Standard plywood consists of an odd number of layers of veneer, with opposed grain in alternate layers, rigidly glued together. The along-the-grain strength reinforces the across-the-grain weakness, and distributes wood strength in both directions. The central layer (core), of veneer or lumber, has the lengthwise grain in the direction requiring strength. In 5-ply, face and core grains are parallel; in 3-ply, they are opposed. Fundamentally the layers should be balanced on the core to avoid uneven stresses. (See Figs. 18 and 19.) The face wood is chosen for appearance; the other layers supply the strength. For most purposes $^1/_4$-in. 5-ply plywood is stronger than $^{13}/_{16}$-in. solid lumber. Plywood is unsplittable, and has more nail- and screw-holding power than solid wood.

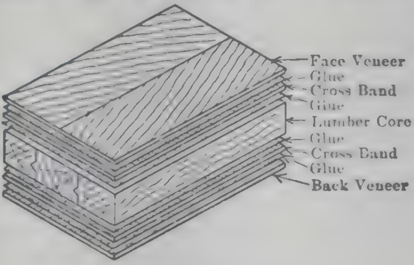

Fig. 18. 5-ply plywood.

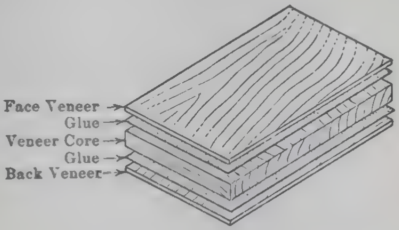

Fig. 19. 3-ply plywood.

The large bulk of plywood is made flat as described. Recent techniques have been developed either to bend flat plywood into simple curvatures or to produce simple and compound curved plywood as it is glued together from veneers. For these techniques, see p. 25-22.

ARRANGEMENT OF EQUIPMENT. Plywood manufacturing falls in two general classes: (1) Factories assembling plywood as a semi-raw material for others. (2) Factories making the ultimate product, as furniture, with an integral plywood department, in which plywood operations are seldom complete. Plywood factories are located preferably with reference to the supply of the bulkiest material, i.e., rotary commercial veneer and core lumber, the face veneer supply being far less important. Propinquity to a consumer furniture area is a doubtful advantage because of the higher wage levels.

Table 9 shows the general sequence of plywood operations. The face veneer preparation, commercial veneer preparation, and lumber core stock converge to a central tempered-air stockroom, where the gluing allocation for each day must be ready not later than the night before. The glueroom is invariably the "bottleneck," has a higher man-hour-ratio per machine than any other plywood operation, and must produce at maximum efficiency.

FACE VENEER. Sliced, half-round, and sawed face veneers are received in flitches, and their suitability for the job in question demands experienced judgment. Unused portions of flitches (lay backs) are a serious problem, often because of wrong size or figure. In general, whole flitches should be charged to a job, leaving lay backs as a by-product; otherwise costs may be seriously distorted.

Highly figured face veneers, if "crinkly," must be flattened before dimensioning. For less fragile species, platen veneer driers are used; it is advisable to dampen fragile veneers and apply gradual pressure with heated boards. In extreme cases, as feathered crotches, veneers are dipped in a dilute glue size to make them more leathery, and are flattened even more gradually. Moisture content should be 5 to 6% after flattening.

Longwood veneers, longer flitches in moderate figure, usually are cross cut on saws in packages of 25 sheets and edge clipped (sheared) with reference to figure matching. Clipped edges are *jointed* (see Veneer Jointers, p. 25-43), planed straight and square, to produce tight joints without cracks. *Stumps* (butts), *crotches*, and *burls* and other highly figured veneers usually are cut both ways in packages on a paper-cutting machine, with an angling shear cut under pressure. Such veneers cannot be jointed as the edges will tear out.

Book-matched veneer comprises two or four adjacent sheets of a flitch, with uniformly (as to grain figure) trimmed edges, laid together to balance the figure as in Fig. 20. It resembles an unfolded 2- or 4-sheet booklet.

Inspection (subinspection as required)

* Cold pressed resin adhesives, with special catalysts, are finding substantial use, followed by baking and storage but eliminating redrying on stickers.

Dimensioned veneers (longwood or book-matched) are *taped* (see Fig. 20) with gummed tape from edge to edge on one surface to hold the pieces in position during gluing. The tape is sanded off later. Taping machines have angling rollers that draw the edges together and press the moistened gummed tape over the adjoining edges. Intricate *combination faces*, of vari-colored species, with or without angling grains, give remarkable effects. Figure 21 shows general arrangement of machine operations in a face-veneer department.

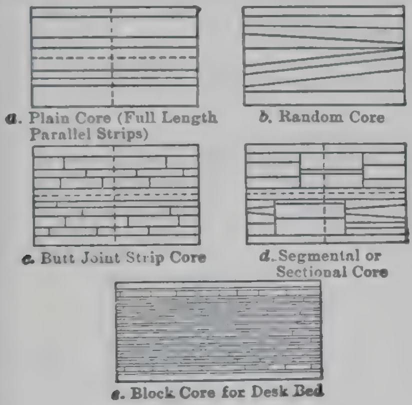
FIG. 21. Arrangement of face-veneer department. ○ indicates position of operator. Numerals show sequence of operations.

Taping machines, applying gummed tape over each veneer joint, are still widely used. They are being displaced by *tapeless splicers,* which push the jointed edges of the veneer together by converging feed chains under heater bars, which cure the resin adhesive in the joint. Such splicing is superior to taped joints, since tape is eliminated from all inner layers and does not have to be removed from face and back layers. Tapeless splicers are not suitable for highly figured face veneers. The tapeless splicers (Fig. 21) take the place of the taping machines (6) and edge gluing (7).

CROSS BANDS, ROTARY CORES, AND BACKS, unless two faces are required, are of commercial rotary veneer, flattened, edge-clipped, sometimes jointed if 3-ply, and taped or spliced as in face veneer. Cross bands under faces, as well as cores in 3-ply plywood, should be one-piece or spliced, but should not be taped, as tape will show through. Back cross-bands, backs and 5-ply cores may be taped or spliced. Commercial veneers, for long runs of standard sizes, often are dimensioned at the veneer mill into whole, half, one-third, two-third, one-quarter, and three-quarter sizes for taping. Moisture content must be kept close to 5%, except that certain layers in film bonding should be 8 to 12%. A commercial veneer department arrangement would be similar to Fig. 21, omitting the swing saw, Sheridan cutter, and edge gluing.

LUMBER CORES generally are used for plywood $^1/_2$ in. and thicker. Five-ply construction is the more stable; face and back veneers in 3-ply usually are thin and do not effectively balance the lumber core. Core lumber is preferably of poplar, chestnut, gum, or other available species. Only one species should be used in a core. Chestnut does not give a sound edge for molding or shaping.



a. Plain Core (Full Length Parallel Strips)
b. Random Core
c. Butt Joint Strip Core
d. Segmental or Sectional Core
e. Block Core for Desk Bed

FIG. 22. Types of cores.

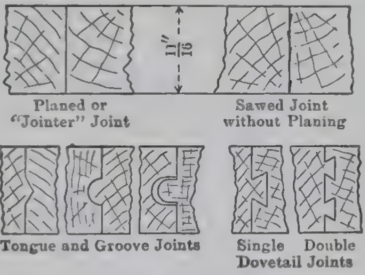


FIG. 23. Types of edge joints in plywood cores.

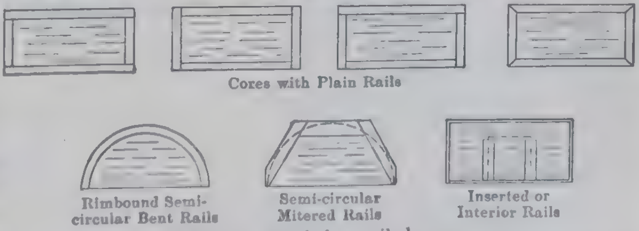
To avoid warp, cores preferably should be made of strips 2 to 3 in. wide. End joints are not objectionable and tend to eliminate twisting stresses. Figure 22 shows various core constructions, and Fig. 23 various core joints. The dotted lines in Fig. 22 indicate multiple cores to be cut apart after planing or gluing, to avoid showing endwise splices. The veneer strips used as glue carriers in core *e* are patented.

Assembled core strips may be glued together by one of several methods. (1) An endless chain *revolving glue clamp*, with a cycle of 30 to 60 min. When the glued core returns to the loading point, it is removed, and a fresh assembly inserted. The application of edge glue swells the lumber, increasing the thickness at the joint, and the glued cores should be seasoned, or equalized in moisture content, before planing. (2) A continuous chain feed *lumber splicer*, in which core strips are placed successively on a rubber-faced chain, pushed between steam-heated platens, and automatically sawed apart into required widths as they emerge from the heated platens. In an alternate feed method corrugated rollers replace rubber-faced chain. (3) A batch or continuous-feed electronic *lumber splicer*, in which the assembled core strips, under edge and face pressure, are passed through a high-frequency electrostatic field to cure the resin adhesive. These core units, in methods 2 and 3, can be planed as soon as the adhesive has attained its grip.



Cores with Plain Rails
Rimbound Semi-circular Bent Rails
Semi-circular Mitered Rails
Inserted or Interior Rails

FIG. 24. Banded or railed cores.

Banded or railed cores (Fig. 24) have a band or rail, of the same species as the face veneer, on one or more edges, to give molded edges the same appearance as the upper surface. These bands are additional core strips, glued on edges or ends, after the ends are trimmed.

All plywood elements, faces, bands, backs, and cores for an order should meet in an air-conditioned central stockroom to avoid subsequent glueroom delays.

Figure 25 shows the arrangement of a core department. Lumber is most economically handled on kiln cars from dry storage and placed on a lumber lift; top of load then always is at machine table height. If, before cross cutting, both sides are rough planed to reveal defects, a 2-side rough planer is placed adjacent to the lift, with the swing cut-off saws next in line. The stock then goes from cross cut to rip saws (see pp. 25-34 and 25-39) for trimming edges and removing wane (tapered and bark edges). If specifications are not too exacting, ripped edges may be glued together without further finishing operations, but quite frequently edges must be jointed true, straight, and smooth for gluing. The sliding matching table (operation 5) is used for the purpose of arranging core strips to distribute stresses, and to rip the last strip to net core width.

FIG. 25. Arrangement of core department. ○ indicates position of operator. Numerals show sequence of operations.

PLYWOOD GLUING DEPARTMENTS (for flat plywood) vary considerably in their arrangement; three types are shown in Fig. 26. In each type a single line is shown, but in multiple lines, where more than one working shift is employed, the ratio of mixers, spreaders, and lay-up tables may be varied. The single lines shown have an approximate average capacity of 5000 sq ft of thin plywood, and a like area of lumber core plywood per 8-hr shift, total 10,000 surface feet.

These types may be described briefly. (*a*) Using standard liquid glues, *casein*, *vegetable* (cassava), *soybean*, *silicate of soda*, etc. Pressing is done at room temperature. The clamped bundles or bales are removed from the press for overnight storage while the glue hardens; they are then stacked up for redrying to remove surplus moisture, and are subsequently unstacked. Operating cycle 2 to 3 days. (*b*) Using liquid resin adhesives, *ureas*, *phenolics*, *melamines*, and also *albumin* glues, where hot pressing is employed, with multiple steam-heated platen presses. Operating cycle, 1/2 to 1 day, including equalizing period for cooling and moisture diffusion. Alternately, certain types of urea resins can be used in room-temperature work, for moderate production requirements, clamped and stored overnight. Redrying is not required. (*c*) Using *phenolic film* adhesives, Tego, hot pressed, and hot plywood usually dipped quickly in water to permit tape removal and to shorten the time of cooling and moisture equalization. Operating cycle as in type *b*. The type of equipment and order of processing steps are shown in Fig. 26.

FIG. 26. Gluing department layouts for flat plywood. ○ indicates position of operator. Numerals show sequence of operations.

Following are the various machines and items of equipment.

Glue mixers are steam and water-jacketed kettles, and have revolving double paddles, usually on a vertical shaft. Horizontal shaft mixers are used to a limited extent. Discharge openings from mixers must be adequate for viscous mixtures and easily accessible for frequent cleaning. For details of preparing liquid glues and their processing requirements, see Section 21, Article 10.

Glue Spreaders. Double-roller spreaders are the rule, applying glue to both sides of the veneer or lumber layer; corrugated metal rollers for casein, vegetable, soybean, and silicate glues; grooved (20 per in.) rubber rollers for all resin adhesives and albumin. Spreading ratios vary from 60 to 90 lb of liquid glue per 1000 sq ft of joint for standard glues and 30 to 50 lb for resin adhesives.

Lay ups, or assemblies, from bottom to top in 5-ply constructions, are back layer without glue, cross-band glue coated on both sides, core without glue, cross band with glue on both sides, and face without glue. Adjacent assemblies are often reversed, with a waxed plywood or metal caul between the two faces to prevent damage. In room-temperature work, bundles are built up, 24 to 30 in. high, on thick head blocks, with another head block on top, clamped with I beams and turnbuckle rods in the press, removed from the press, and stored overnight for hardening of the glue. In hot pressing, either liquid or film, a lay-up table is provided in front of the hot press, where assembled units are placed between aluminum cauls for loading into the hot press.

Pressures for room-temperature work, often called cold pressing, are from 100 psi for softwoods to 150 lb and up for dense hardwoods. For hot-press work, where thickness compression may be of the order of 5 to 10%, pressures range from 150 to 250 lb, respectively.

Pressing time for room-temperature work is 4 to 6 hr, usually overnight; for hot pressing, 5 to 30 min, depending on thickness of the assembly. After removal from the hot press, plywood is stacked solid to cool and equalize.

Redrying is required for most standard glues where the solids content of the mixture averages 30 to 40% and plywood after pressing may have 15 to 20% moisture content. Redrying is not required for resin adhesives with 50 to 60% solids content and pressed at room temperatures. Hot-pressed plywood tends to be overdry and needs time to reach equilibrium moisture content. Phenolic bonded plywood is often dipped in water to shorten the cooling and equalizing period, and to reduce warping in thin plywood. Such plywood should be dipped quickly when hot and piled solid.

While steam heat is usually employed for hot-pressed plywood, as it is easily available in woodworking factories, some installations use high frequency or resistance heat from electrical sources. For details, consult manufacturers of such electrical equipment.

DIMENSIONING for flat plywood is done preferably on double cross cut and double rip saws of the double-end tenoner type (p. 25-46), in which a pair of endless chains, with lugs, carry the plywood through the saws. One saw head is fixed, and the other adjustable to the size required, usually up to 96 in. Many other types of saws and saw tables may be used for this work. Ripping usually precedes cross cutting. For center matched plywood faces, pointers on the machine are used to insure proper centering of face veneer joints.

Sanding. Plywood is sanded to remove the veneer tape and to prepare surfaces for filling, staining, and lacquering. Usual operations are: (1) Preliminary sanding of the back side of the plywood on a roll or endless belt sander, to clean it and remove most of the tape; other back sanding seldom is necessary. (2) Similar sanding on the face, taking care that high spots do not sand through. (3) Finish sanding on belt or stroke sanders, with very fine sandpaper. Some authorities advocate doing all sanding of plywood with highly figured face on belt or stroke sanders, to prevent the waste of sanding-through by careful operation. Figure 27 shows a typical arrangement of a dimensioning and sanding department.

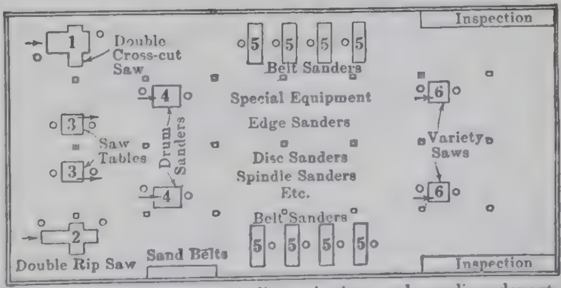

FIG. 27. Arrangement of dimensioning and sanding department. ○ indicates position of operator. Numerals show sequence of operations.

Redimensioning sometimes is practiced when plywood is glued and sanded in multiples, as with small parts, where separate handling would greatly increase costs.

Inspection. The chief inspector usually is stationed between the sanding and crating departments, with subinspectors only in the face veneer and lumber core departments.

CURVED PLYWOOD. Flat plywood can be bent into several types of simple curvature more cheaply than it can be curved during the gluing process. Alternately veneers can be bent and made into simple and compound curvatures during the gluing process. The principal methods are these:

1. Flat plywood bent into *simple* curvature, with or without heat.
   - *a.* Without recessed backs on concave side.
   - *b.* With recessed backs on concave side.
2. Veneers bent into curves during the process of gluing into plywood.
   - *a.* *Simple* curvature, with or without heat.
   - *b.* Moderate *compound* curvature, formed plywood, between pairs of heated dies with unidirectional pressure.
   - *c.* Wide range of *compound* curvature, molded plywood, using one rigid die and omnidirectional pressure from flexible bags, usually with heat.

Combinations of these methods are often advantageous, as suggested in the following descriptions.

CURVING FLAT PLYWOOD. Flat plywood, up to $^1/_4$ in. and sometimes up to $^3/_8$ in., can be bent into gradual curvature with relatively large radii, without steaming or otherwise heating, but such curves must be held in place by framework or grooves. Much depends on the grain direction of the veneer layers and their relative thickness. There is a distinct limit to which such simple curvature can be made without preliminary steaming and drying under pressure in some type of curved forms. When heat is employed, the bending press shown in Fig. 28, or the heated endless bed mechanism in Fig. 43, may be substituted for the curved forms. Under such heat bending, plywood curved from flat sheets is not dimensionally stable and tends to open or close somewhat, requiring bracing, but not to the same extent as plywood bent without heat.

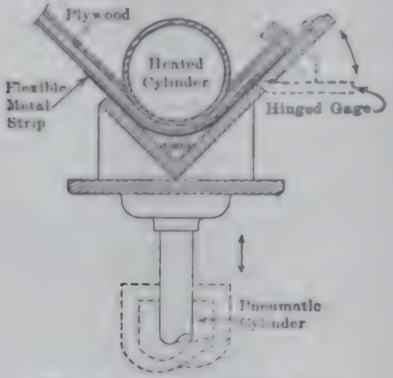

FIG. 28. Plywood bending press.

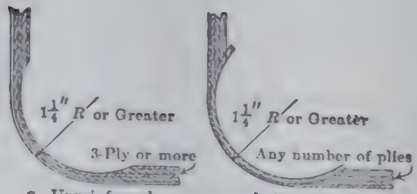

a. Unreinforced *b.* Reinforced

FIG. 29. Recessed backs for bending thin plywood.

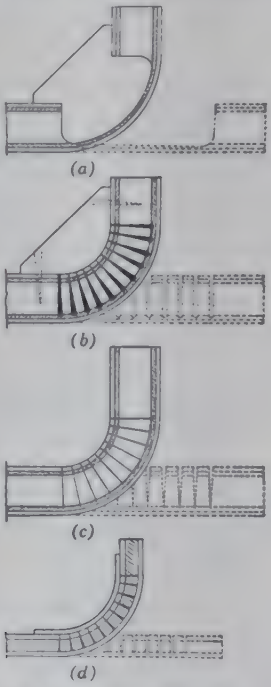

FIG. 30. Recessed backs for bending thick plywood.

Another technique is to recess the plywood on the concave side, with either a wide groove behind the entire curved area or a series of saw slots, both as shown in Figs. 29 and 30. Curved plywood with such recessed backs is quite limber and requires bracing by a supporting framework, by reinforcing strips of veneer glued in place, or by supporting blocks screwed or nailed in position. Moderate steaming is often used to soften the convex veneer layers over the recess and reduce danger of wood fracture. Where veneer strips are glued for such reinforcing, heat curing resin adhesives may be employed in the bending press shown in Fig. 28. When either reinforcing veneers or mechanically fastened strips are employed, the curves will be dimensionally stable and will not require supporting grooves or framework.

Where plywood is to be steamed for bending, or reinforcing veneers are to be attached with a heat curing resin adhesive, such plywood must be selected for heat and moisture resistance, preferably made with a phenolic or melamine resin adhesive (see Section 21, Article 10), although urea resins can be used under limited steaming or heating. In some cases, where heat only is employed, casein glued plywood may be used.

CURVING PLYWOOD DURING GLUING ASSEMBLY. As a practical manufacturing problem, only such curves can be economically bent in plywood assembly operations as can be formed in hydraulic presses with vertical pressure. There is a definite limit to the extent of curved segments that can be glued effectively. Figure 31 shows that, with a given direct pressure A, a 90-degree segment will have a pressure of approximately $^2/_3\ A$ at its extremity B, while a 120-degree segment will have a pressure of $^1/_2\ A$ at the extremity C. It is possible to bend a 120-degree segment successfully, and it will include enough more than a quadrant to produce grooved and well-fitted corners. A 180-degree segment would have no vertical pressure component at D; pressure would be derived only from the snugness of the forms. The limit of 120-degree segmental angle applies to both simple and compound curved surfaces.

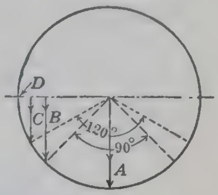

Fig. 31. Diagram showing how edge pressure (at B and C) diminishes with angle subtended, in bending plywood.

Figures 32 and 33 show typical curved segment plywood constructions. The thickest layers of veneer are bent with the grain, and thin sheets only are bent against the grain. Increasing the number of plies (Fig. 32) often facilitates the bending operation, and reduces the thickness of the layers.

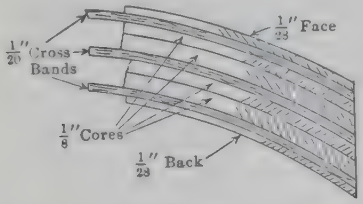

Fig. 32. Typical curved construction, thick plywood.

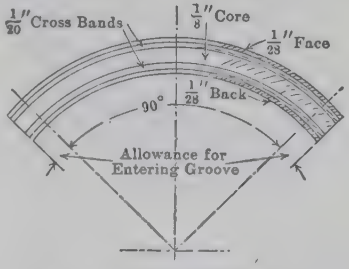

Fig. 33. Typical curved construction, thin plywood.

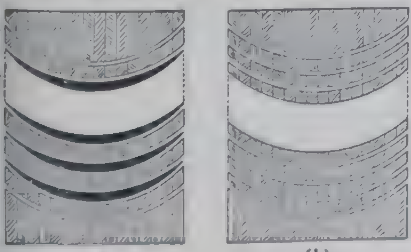
When curved plywood with lumber cores is required, such cores can be band sawed from laminated lumber blocks of suitable size, as shown in Fig. 34. In the left sketch (*a*) the lumber core units are of uniform thickness, on a radial line, and shaded crescent-shaped fillers are sawed out and employed for pressure purposes. The right sketch (*b*) sacrifices the feature of uniform thickness and eliminates the filler, as is practical for many designs. In either case it is important that the saw kerf be wide enough to accommodate the several layers of veneer that are inserted for curved faces and backs. Crossings are used, are coated on both sides with glue, and the assembly laid up in the usual manner. The top and bottom segments are used against the head blocks, and the bale is hydraulically pressed and clamped as in flat plywood.



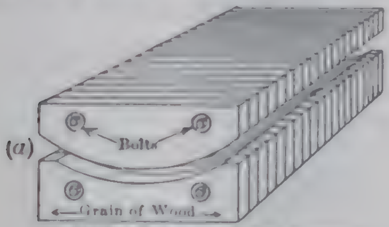
(*a*) (*b*)

Fig. 34. Band-sawed lumber cores for curved plywood.

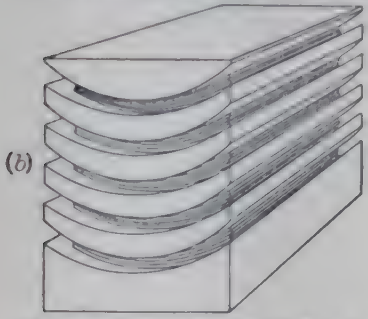
Adhesives for Bonding Plywood Curves at Room Temperature. Plywood bending operations can be carried out with a wide range of liquid glues or adhesives, vegetable (cassava), casein, or any of the room-temperature resin adhesives. A quick-setting glue, with special accelerator, is desirable to permit the re-use of forms and dies. Standard hydraulic presses, I beams, and clamping bolts are employed, as all forms should have square end blocks for firm clamping (see Figs. 34 and 35). After removal from gluing forms, the curved plywood should be racked in curved skeleton forms and weighted during redrying.

Hot Press Adhesives for Curved Plywood. Curved plywood can be made with much shorter operating cycles in hot presses, where pairs of heated metal dies are used. Such dies must be accurately shaped and can be used only for a given thickness of plywood. These dies may have heating units incorporated, steam or electric, or may take their heat from the platens of a hot press, to which they can be firmly attached. The same limits control the extent of simple plywood curvature from a unidirectional pressure piston as outlined on p. 25-22. Synthetic resin adhesives are preferred for this type of work (see p. 21-23) and permit operating cycles of 5 to 30 min.

FORMED PLYWOOD refers to plywood pressed to shape between pairs of heated metal dies during the gluing operation, but having only a moderate degree of compound curvature. Wood, when heated, acquires a certain degree of ductility, and can be pressed into such shapes as Toastmaster trays, in which the center is depressed below the surrounding rim, or a barrel stave, with both body and bilge curves combined; or a crowned or dished head, as for a barrel or wardrobe trunk. Such formed plywood can be compared with molded plywood, described below, in which compound curvature is much more pronounced.



Single Wood Forms for Cold Pressing
(For Hot Pressing made integral of Aluminum)



Multiple Aluminum Forms for Cold Pressing

FIG. 35. Platens for bending plywood.

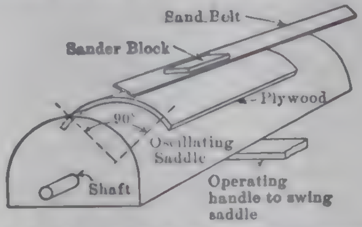


FIG. 36. Method of sanding convex plywood.

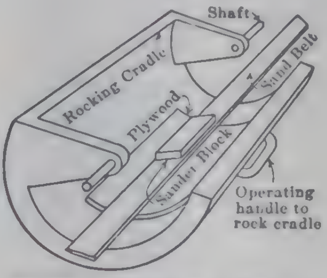

FIG. 37. Method of sanding concave plywood.

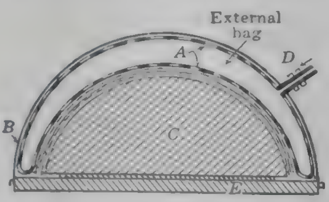
FLEXIBLE PLYWOOD may be made 3-ply with a very thin core, and thick loosely cut outsides. It is suitable only for rough work that is to be painted, and is not adaptable to figured face woods.

SANDING OF CURVED SHAPES presents some unusual problems. Good results may be obtained by attaching either the saddle or cradle (Figs. 36 and 37) to a belt sander to facilitate sanding either the inside or outside face of curved plywood.

MOLDED PLYWOOD. The flexible bag pressure process, developed during the 1930's, employs a rigid member as half of the mold (matrix, form, or die) and a nonrigid or flexible bag as the other half of the mold. By various methods of inflating or deflating, the pressure can be applied in all directions, in net effect, perpendicular to tangents on all curved plywood surfaces. This gives great versatility to the resulting plywood and permits the production of intricate plywood shapes of various degrees of compound curvature, such as boat hulls, airplane fuselages and wings, reflectors, domes, hollow floats, and stream-lined fuel tanks. Since pressure is wholly flexible, the thickness of the plywood can be increased for strength or decreased for weight reduction. The average pressure requirements are less than for flat plywood.

The veneer strips, of which the various layers are composed, are tailored to shape; for example, strips like small sections of an orange peel for a hemisphere, or tapering strips for a boat hull. These strips are coated on both sides with a suitable resin adhesive; this coating is dried before cutting to shape. The coated strips are properly assembled, laid up, on a male form or dummy, and temporarily fastened in place by tacks, tape, or staples, before pressure is applied. During the pressure application, the veneer strips are forced into place, and as the pressure continues, are firmly bonded by the resin adhesive at the proper temperature. A resin adhesive for this purpose must have a relatively long flow period at around 180 F, considerably below the curing range, to permit the veneers to become properly nested before the cure takes place, usually around 250 F. The bags are of synthetic or natural rubber that can be clamped tight against leakage. The pressure medium is usually steam, sometimes supplemented by compressed air, although this combination deteriorates the bag more rapidly than steam alone.



(*A*) External bag

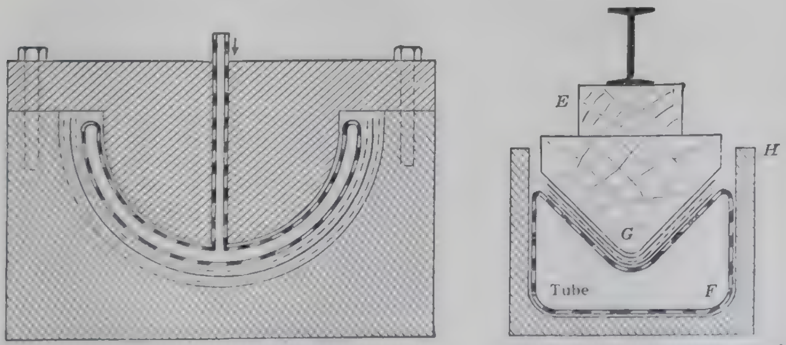
(*D*) Vacuum-pressure method with shell mold (Vidal)



(*E*) Pressure cushion bag

(*F*) Tubular pressure, multidirectional

Fig. 38. Omnidirectional pressure applications in making compound curved plywood by flexible bag (fluid) pressure.

There are many ways of applying this omnidirectional pressure, some of the more important being illustrated in Fig. 38, and briefly outlined as follows.

A. *External bag, inflated* against an enclosing outer shell. Mold of male type, solid and may be heated. Assembly laid up directly on mold.

B. *Internal bag, inflated* against a closed mold, which may be heated. Mold of female type, assembly usually laid up on a male dummy and inverted into the mold.

C. *Autoclave process*, plywood assembled on the male mold, enclosed within bag, which is deflated by vacuum before being placed in autoclave. Autoclave requires mechanically manipulated doors, for quick opening and closing and tight sealing. Autoclave pressure supplements the vacuum within the bag. Efficient method for large complicated curvature, but with an operating cycle of 2 to 3 hr.

D. *Autoclave process*, as in *C*, except that plywood assembly is laid up flat as a blanket, or upon a male dummy. Plywood assembly transferred to the female mold, usually a braced steel shell. Vacuum-pressure process as in *C*.

E. A modification of *B*, an *internal inflated* bag against a closed mold, in which the upper male mold extends to within 2 or 3 in. of the lower female mold. This upper mold is faced with an expandable bag so that inflation time is reduced to a minimum. Excellent process for fast production schedules, approximately 10 to 15 min per cycle.

F. *Tubular pressure*, in which the flexible bag consists of a section of 2 1/2-in. inside diameter fire hose, which is inflated by steam or hot water. Ideal for relatively simple shapes where curvature is chiefly in one plane. Adaptable and simple for small moldings, angles, coves, pilasters, etc., with a short operating cycle as in *E*.

Various combinations of these methods as well as other flexible pressure combinations are also used to a lesser extent. These various methods of making molded plywood assumed great importance in World War II (1942–1945), when thin light metals were scarce and plywood was found to be an acceptable alternate. They continue to give decided promise of extensive industrial use for civilian plywood products.

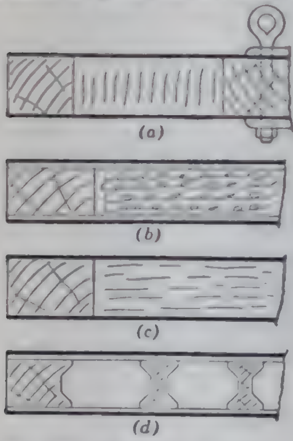


FIG. 39. Sandwich constructions: (*a*) metal faces, end grain balsa cores, solid wood inserts for bolts; (*b*) plywood faces with sponge rubber or other foamed core material; (*c*) Compreg faces with side grain wood cores, (*d*) Plymetal faces with hollow cores, using wood strips for center supports. Honeycomb paper cores may be used in similar fashion.

MODIFIED PLYWOOD. Standard and conventional plywood consists wholly of wood layers, with the wood grain of alternate layers crossed. There are many comparable constructions, in which other materials may be used for some or all of the layers, in which case less attention is paid to the cross-laid effects. Adhesives must be properly selected and adapted to the various materials, for which information should be secured from resin adhesive manufacturers.

Another technique, developed chiefly during the war emergency, is to impregnate one or more layers of wood or other material with a synthetic resin to facilitate densification, as well as to increase hardness and strength. Under normal pressures, up to 500 psi, this densified plywood product is called Impreg; under pressures of 1000 to 2000 psi, Compreg, Pregwood, etc. When layers are of paper or like products, the name Papreg is used.

Metal layers, with special metal-to-wood adhesives (see Section 21, Article 12) may be one-side, two-side, or internal, and are called Plymetal. It is widely used for transportation equipment.

Sandwich constructions (see Fig. 39) consist of a low-density or hollow core, with normal or high-density plywood exteriors or with metal or other high-tensile-strength material as coverings. Solid wood blocks are inserted in the core for fastening purposes as shown.

Decorative veneer faces are applied to many types of insulating fiber boards, to asbestos board, to metal fireproofing partitions, and to plaster surfaces, all to harmonize with other wood interiors under a variety of trade names.

Paper faces are applied to plywood, of various grades and for many purposes; on Douglas fir plywood, for improved protection and painting properties; on industrial plywood, to permit die punching; on plywood box shooks, for strength, tightness, and appearance.

Laminated resin products, paper, cloth, glass cloth, etc., are used as plywood faces for kitchen, hospital, and store equipment.

In general, these modified plywood products are made flat, usually by hot pressing, employing suitable resin adhesives, in much the same way as standard plywood. However, the supplementary methods described of bending and curving plywood apply to certain of these combination laminated materials.

Manufacturers of Plywood Equipment. The following are some of the leading makers: Merritt Engineering and Sales Co., Lockport, N. Y.; Chas. E. Francis Co., Huntington, Ind.; Williams White and Co., Moline, Ill.; Black Brothers Co., Mendota, Ill.; Plycor Co., Chicago, Ill.; Columbia Machinery and Engineering Corp., Hamilton, Ohio; Union Tool Corp., Warsaw, Ind.; G. M. Diehl Machine Works, Wabash, Ind.; Handy Manufacturing Co., Chicago, Ill.

9. WOOD FINISHING

The term *finishing* generally includes *polish sanding, filling, staining, lacquering,* and *waxing.* The preliminary sanding operations (see p. 25-16) precede the cabinet assembly stage. Final *polish sanding*, either by hand or by mechanical devices, after cabinet assembly, should leave a very smooth surface which will not place an undue burden on the filler. Many factories sponge before polish sanding to raise the grain, and cause the slender sander shreds to become more or less erect for removal in sanding. Since sponging tends to clean out the wood pores, they must be filled even with the surface, especially in open-grain woods like oak.

Filler. Standard fillers usually consist of silex and other ingredients, in a paste form, diluted with naphtha. They are brushed on, allowed to dry partially, and rubbed into the pores with a circular motion. The surplus is wiped off, without removing any filler below the finished surface. Defective filling is indicated by pockmarks, when too much filler has been wiped off, or the depressions are too open for the filler to stick. Correct results should follow the first filling; deficiencies may be remedied by repeating the process. In modern finishing technique, filler replaces the many coats of varnish formerly used.

Stain. After filling, stain is applied (this sequence is sometimes reversed), usually with a spray gun, to obtain the desired color. The color may be that to which the species will normally mellow from air exposure or may be a purely artificial color. Stain and filler make end wood appear darker than side wood, because of the volume of penetration. Care must be taken to limit the amount of stain on colored areas. Stains are distinguished by the solvent as: (1) *Water stains*, erroneously called acid stains. They are the most permanent in color, but darken a trifle as the wood ages. They raise the grain more than other stains. (2) *Spirit stains*, dissolved in alcohol. They dry more quickly, fade easily, but do not raise the grain. (3) *Oil stains*, which are not extensively used in high-grade furniture because they "bleed" with the solvents used in later lacquer applications. In cheaper finishes, filler and stain are combined and applied in one operation; results are inferior. Water stain and aniline dyes, made from coal tar, are preferred for best all-round results.

Varnish, formerly a widely used final finish, has largely given place to lacquers, which have much shorter drying cycles.

Lacquer. Many clear lacquers, of similar characteristics, are gradually developing into high-solid, quick-drying coatings. They perform more satisfactorily than varnish in drying ovens, and can be varied in constituents to meet the conditions of exacting service. A large number of them are made from a synthetic resin base, and many are formulated to withstand, without discoloration or blister, water, heat, and alcoholic solutions. The number of coats applied varies, in general, with the degree of permanent finish desired. Consult the literature of the well-known makers of finishing materials for further details.

Force dry finish is a recently developed technique consisting of a combination of synthetic resins and other chemical ingredients that can be dried rapidly at elevated temperatures, 140 F ± in 60 to 90 min. It permits the use of high solids content, 40 to 50%, and thus requires fewer coats for a given weight of finish. The shortened time schedule facilitates conveyorized finishing systems, thus reducing the time of handling. This force dry finish method may be applied over a lacquer sealer or used as a self-sealer; in the latter case a subsequent top coat and a second baking are required. It may be used for gloss, semigloss, or as a conventional rub and polish finish in the regular manner. Consult the literature of the well-known makers of finishing materials for further details.

Wax is one of the oldest finishes known. It is applied as a paste over about two coats of shellac. The shellac is applied on properly stained wood, which then usually is sanded. After the wax is dry, it is rubbed to a dull polish. If rewaxed occasionally an excellent and easily maintained finish is obtained.

Other finishing materials are *colored lacquers* and *enamels* and various trade-marked products, some of which are of excellent quality. Their application is similar to the process outlined above. Usually a less expensive undercoater is applied, followed by the finish coats. Care must be taken to prevent the solvents used in the successive coats from bleeding the preceding coats, thus producing muddy colors and sticky effects.

ARRANGEMENT OF FINISHING EQUIPMENT. Figure 40 shows a typical finishing department. Finishing rooms must be dustfree, and thoroughly fireproof, since many solvent fumes are highly explosive. All fan motors must be sparkproof. Conveyor chains and other moving parts should be guarded against friction and sparks. Fully air-conditioned finishing rooms permit standardization of drying conditions and make them independent of climate and weather.

Many finishing rooms have overhead conveyors, from which semifinished units are suspended, progressing successively from station to station in the finishing cycle.

Some cheaper products are finished, in whole or in part, by dipping in tanks. Dipping applies especially to stains and sealers. Provision then must be made to drain and drip, to avoid excess material forming beads in objectionable locations.

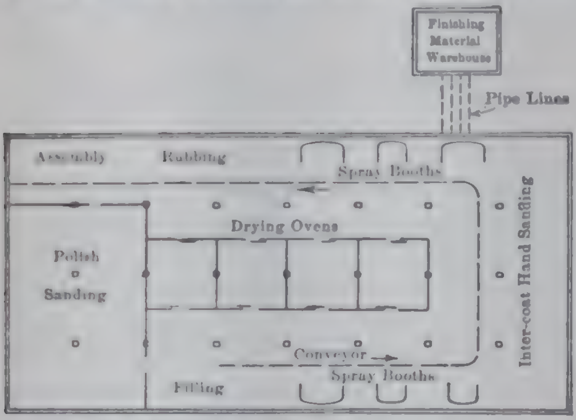

Fig. 40. Arrangement of finishing department.

The polish sanding department, immediately preceding the application of finishing materials, should be separated from the spray booths by airtight partitions to reduce dust hazards. Drying ovens should be centrally located, with several separately controlled, well-ventilated rooms to provide conditions required for drying filler, stain, undercoater, and lacquer. Finishing materials are best stored in a separate firesafe building, where all standard mixing can be done. All material should be piped and pumped to individual booth locations.

Hand sanding often is necessary between coats to remove small pimples that form around small particles of dust and undissolved solids. Many better grades of products require *rubbing*, to produce a dull nonlustrous surface. On irregular shapes, rubbing may be by hand or by holding the work against a cushioned revolving spindle. For table tops and similar products, mechanical stroke rubbers, with reciprocating cushion pads, are used. Rubbing down a good grade of lacquer gives a much better finish than semigloss lacquer, which lacks durability. The usual rubbing compounds are powdered pumice and oil, mineral oil, and diatomaceous earth.

Spray booths are almost universally used in finishing rooms. They are closely regulated by local ordinances, requiring direct fan connections to outdoors, to preserve health of operators and to reduce fire hazard. Spray booths generally are equipped with automatic revolving tables, with pneumatic vertical travel, to give access to legs, backs, and under parts.

Spray guns are atomizers, operated by compressed air at 75 to 100 psi. Guns giving smooth, glasslike fan sprays are available that cover up to 60 in. width. Air volume may vary from $^1/_2$ to 50 cu ft per min. Dual, triple, and quadruple heads are available for attachment on spray guns for special products. Consult manufacturers' literature for details of spray booths and spray guns.

10. WOOD PRESERVATION

Preservatives that lengthen the life of wood exposed to decay, insects, marine borers, and fire are: (1) preservatives of an oily nature injected into wood as such; (2) chemicals injected into wood in water solutions; (3) petroleum oils fortified with toxic chemicals; (4) fire-retardant chemicals injected into wood in water solutions. Intelligent selection for a particular service greatly prolongs usefulness of wood, with excellent ultimate economy.

PRESERVATIVE OILS. Coal-tar Creosote. As used in wood preserving, creosote is a distillate of coal tar produced by high-temperature carbonization of bituminous coal. It is the most generally adaptable preservative for use with wood in contact with ground or situated under water. Its principal advantages are its general widespread use and availability and its highly permanent quality in service. Its principal disadvantages are its sometimes objectionable odor and appearance and the fact that it is difficult to work with, especially in the hot sun. It cannot be painted successfully. The odor is not strictly objectionable except where it may be transferred to stored food products. Freshly creosoted wood is inflammable, but after it has seasoned it is no more inflammable than untreated wood. Specifications for creosote and its blends for both pressure and nonpressure processes are listed under *Specifications* at the end of this article.

Creosote and Coal-tar Solutions. Occasionally creosote is diluted with coal tar for treating items, except poles, that are generally creosoted. The blends most commonly used contain 20 to 30% coal tar.

Creosote-petroleum Solutions. Creosote is also blended with petroleum quite extensively for the treatment of crossties used in the arid regions of the West. On the average, blends contain 50% petroleum, and although the toxicity is reduced, the treated products are cheaper and possess a measurable resistance to checking.

Water-gas Tar Creosote and Wood-tar Creosote. These are somewhat less effective preservatives and used only occasionally.

CHEMICALS IN WATER SOLUTION. Chemicals injected into wood in water solutions have the distinction of leaving the wood clean, and although its color might be changed, it is readily paintable after it has dried. Their principal use is for sawed lumber in structures which must be painted and for general indoor and outdoor construction where clean treatment is necessary. Such uses include wet-process mill roofs, piers and boardwalks, bridges and highway structures, mine timbers, refrigerated buildings, sanitary works and water supply, and stadiums.

Zinc Chloride. This chemical was used quite widely several years ago, but it has dropped off in favor of improved preservatives. It was used in a 3 to 5% solution which left about 1 lb of the dry chemical per cubic foot of wood. It is still covered in some specifications. See under *Specifications* at end of this article.

Chromated Zinc Chloride. The chromated zinc chloride, which has replaced straight zinc chloride, contains not less than 17.5% sodium dichromate. The American Wood-Preservers' Association requires a net retention of $^3/_4$ lb of dry chemical per cubic foot of wood in their specifications. See also under *Specifications* at the end of this article.

Wolman Wood Preservative Salts. The Tanalith compound is the most widely used of the Wolman wood preservatives. It contains 37 $^1/_2$% sodium chromate, 25% disodium hydrogen arsenate, 25% sodium fluoride, and 12 $^1/_2$% dinitrophenol. It is noted for its anticorrosive qualities. Lumber treated with Tanalith can be successfully glued with phenol or resorcinol glues. It makes no difference whether the wood is treated first, then glued, or whether it is treated after being glued; a satisfactory bond will result. The American Wood-Preservers' Association, in its specifications, requires a net retention of 0.35 lb of dry chemical per cubic foot of wood. See also under *Specifications* at the end of this article.

Zinc Meta Arsenite. This preservative has been used somewhat in the past, but at present commercial treatments are not available. The American Wood-Preservers' Association specify a 0.35 lb per cu ft minimum net retention for this preservative. See also under *Specifications* at the end of this article.

Greensalt. This preservative, also known by the trade name of Erdalith, is a mixture of 56% sodium or potassium dichromate, 33% copper sulfate, and 11% arsenic acid. It becomes highly permanent in the wood and is especially effective against fungi which attack wood in ground contact. It is a clean, paintable preservative used for the same purposes as creosote. See under *Specifications* at the end of this article.

Miscellaneous. There are other water-borne preservatives in use which are not listed in the American Wood-Preservers' Association specifications and deserve mention. They are (1) Chemonite, which is copper-arsenate with a small excess of copper hydroxide in a strongly ammoniacal solution; (2) Celcure, which is a slightly acid aqueous solution of a soluble chromate and a soluble copper salt; (3) Osmose, a fluoride-phenol-chromate mixture. Other preservatives, which have practically disappeared from use, are straight sodium fluoride, mercuric chloride, copper sulfate, and arsenic salts.

PETROLEUM OILS FORTIFIED WITH TOXIC CHEMICALS. The chemicals pentachlorophenol, copper naphthenate, and zinc naphthenate are used in petroleum solutions of various types. For products such as millwork, the petroleum is of the volatile type, so that the wood will eventually take paint. When used for poles, crossarms, etc., the petroleum is on the non-volatile type. See under *Specifications* at the end of this article.

FIRE-RETARDANT CHEMICALS IN WATER SOLUTIONS. Fire-retardant chemicals are injected into wood in chemical retentions five to ten times as great as the toxic salt preservative chemicals. A heavy retention, 3 to 6 lb per cu ft, is needed to delay ignition and check the spread of fire over wood surfaces. The important fire-retardants, as listed in the Navy Department Specifications, are as follows:

Type I. Consists of a mixture of 3% sodium dichromate, 78% ammonium sulfate, and 19% ammonium phosphate (either monobasic or dibasic).

Type II. Consists of a mixture of 10% diammonium phosphate, 60% ammonium sulfate, 10% anhydrous sodium tetraborate (borax), and 20% boric acid. This formula is used under the trade name Minalith.

Type III. Consists of a mixture of 60% anhydrous sodium tetraborate and 40% boric acid.

Type IV. Straight zinc chloride or chromated zinc chloride.

Type V. Any undisclosed formula as may be acceptable by performance tests.

PREPARATION OF WOOD FOR TREATMENT. Before adequate treatment can be obtained by any of the commercial methods in common use, freshly cut wood must be properly prepared for processing by the following methods.

Peeling. As bark is impermeable to liquids, it must be peeled from round timbers to facilitate impregnation.

Air Seasoning or Kiln Drying. Because green wood is harder to treat than dry wood, it should be dried before treatment.

Preframing. Where practicable, all cutting, framing, boring, etc., should be done before treatment.

Incising is an improved method of increasing penetration in species that are hard to treat. The timbers are passed through a machine, in which teeth, on horizontal and vertical rollers, slit into the wood $^1/_2$ to $^3/_4$ in.

Steam Conditioning. Where it is either impracticable or undesirable to air-season or kiln-dry lumber before treatment, a steaming-and-vacuum process is commonly employed. This involves steaming the lumber in the pressure-treating cylinder for several hours, at 7 to 20 psi gage pressure, after which a vacuum is drawn for an hour or more. The effect of the vacuum is to lower the boiling temperature in the cylinder and facilitate evaporation of moisture from the wood.

Boiling under Vacuum. Another substitute for air-seasoning or kiln-drying before creosote treatment is boiling the wood in creosote under a vacuum. This process is called Boultonizing. The standard cylinder charge is heated in the preservative oil at 180 to 210 F under vacuum, which causes the water in the wood to vaporize off.

WOOD PRESERVING PROCESSES. Nonpressure Processes. Methods of treating that do not use pressure do not result in as thorough impregnation as pressure processes, but they are the only possible means of treating where pressure equipment is not available or where pressure treating is impracticable. The results of nonpressure processes, with the exception of the hot and cold bath, are only fair at best, but are no doubt better than no treatment at all. Nonpressure processes include the following: (1) Hot and cold bath, which is the most effective nonpressure process. The wood is heated in preservative in an open tank for several hours, and then cooled in preservative for a like period. In the first bath, air is greatly expanded by heating, and in the cold bath this air contracts and draws the preservative into the wood. This is an important process in butt treating cedar poles. (2) Brush and spray treatments. (3) Dipping. (4) Steeping. (5) Charring. (6) Diffusion process.

Pressure Processes. These are the most effective methods of treatment. The lumber, or round timbers, separated to expose all surfaces, are placed on steel tram cars and run into a long steel cylinder, which then is closed and filled with preservative under pressure. The preservative pressure may range from 85 to 175 psi, and the temperature may range from 100 to 200 F. The full-cell and empty-cell are the two important pressure processes.

1. *Full-cell Process.* This process is preferable for both oil and water solutions, when the maximum absorption of preservative is desired. The steps in the process are: (1) charging the cylinder; (2) applying a preliminary vacuum (at least 22 in. of mercury) to remove all possible air from the cylinder and wood; (3) admission of preservative to the cylinder without breaking the vacuum; (4) application of pressure until required absorption is obtained; (5) withdrawal of preservative; (6) a short final vacuum or standing period to free the charge from dripping preservative.

2. *Empty-cell Process.* This process is preferable when the maximum penetration is desired with only a moderate amount of preservative and is practicable only with easily treated lumber. It is generally called the Rueping process. It differs from the full-cell process in that instead of an initial vacuum being applied to the charge, initial air pressure of 25 to 100 psi is applied. The preservative is then introduced while the charge is still under air pressure. After the charge has been treated and pressure released, the trapped air in the wood will force part of the preservative out. The charge, therefore, will be deeply penetrated, but will have only a moderate amount of preservative, which reduces the cost of treating.

FIELD TREATMENT. Insofar as practicable, lumber and timbers should be framed, bored, and cut to length before treatment, and field work of this character should be limited to a minimum. The use of cant hooks, pickaroons, peavies, and other pointed tools, except end hooks, should not be allowed in handling treated wood. The greatest care should be exercised in unloading and handling so as not to expose any untreated wood. All timbers which must be cut or bored after treatment should have the surfaces so exposed covered with hot preservative solution. Where cut, the surfaces should be painted thoroughly with two coats of hot preservative. Where holes are bored, they should be poured full of hot preservative. Horizontal holes may be filled by pouring the preservative in them through a bent funnel. The use of a special instrument for applying the preservative to the holes under pressure will result in much better protection.

DRYING AFTER TREATMENT. When wood is treated with water solutions, it is desirable to air-season or kiln-dry it after treatment and before it is installed, to insure against shrinkage and other bad effects of wet wood. When the lumber is to be painted, it is imperative that it be dry when the paint is applied.

SPECIFICATIONS FOR WOOD-PRESERVATION TREATMENTS. A summary of the various specifications for the preservative treatment of wood is given in the following paragraphs.

American Wood-Preservers' Association. Coal tar creosote, P1-49. Creosote-coal tar solutions, P2-48. Creosote-petroleum solutions, P3-48. Zinc chloride, P5-49. Chromated zinc chloride, P5-49. Wolman wood preservative (Tanalith) P5-49. Zinc meta arsenate, P5-49. Greensalt, P5-49. Pentachlorophenol, P8-49. Copper naphthenate, P8-49.

Treating Methods. Lumber and timbers, T1-49 and T2-49. Piles, T1-49, and T3-49. Poles, T1-49, and T4-49. Posts, T1-49, and T5-49. Crossties, T1-49 and T6-49. Wood blocks, T1-49 and T7-49 Pole butt, T9-49.

American Railway Engineering Association. Committee 17. Coal tar creosote (1946). Creosote-coal tar solutions (1946). Creosote-petroleum solutions (1945). Zinc chloride (1926). Chromated zinc chloride (1948). Wolman wood preservative (Tanalith) (1948).

American Association of State Highway Officials. Coal tar creosote, M-133-42. Creosote-coal tar solutions, M-133-42. Creosote-petroleum solutions, M-133-42. Zinc chloride, M-133-42. Chromated zinc chloride, M-133-42. Wolman wood preservative (Tanalith), M-133-42. Zinc meta arsenate, M-133-42.

Federal Standard Stock Catalog. Coal tar creosote, TT-W-556a. Creosote-coal tar solutions, TT-W-566a. Creosote-petroleum solutions, TT-W-568. Zinc chloride, TT-W-576. Chromated zinc chloride, TT-W-551. Wolman wood preservative (Tanalith), TT-W-573. Zinc meta arsenate, TT-W-581. Celcure, TT-W-546. Chemonite, TT-W-549. Pentachlorophenol, TT-W-570.

Treating Methods. TT-W-5716.

American Society for Testing Materials. Coal tar creosote, ASTM designation: D 391.

American Telephone and Telegraph Company. Greensalt, AT-6993.

U. S. Department of Commerce. Zinc naphthenate, Commercial Standard, TS-4895.

Navy Department Fireproofing Specifications. Types I-V, 51 C 38, and 51 C 40.

Treating Methods. Federal Specification TT-W-571b.

11. BENDING SOLID WOOD

Several processes of bending are in use. The technique differs between solid wood and plywood (see p. 25-22) as the fiber strain usually is much greater and more unbalanced in solid wood. Fundamentally, in bending wood strips the individual wood fibers tend to slide by each other slightly; outside fibers are stretched under tension, and inside fibers are compressed.

WET BENDING IN SOLID WOOD. Any wood part is more easily bent when soaked or steamed to a point of thorough saturation. Consequently, bending is better and breakage less in steamed or cooked air-dried lumber than in kiln-dried lumber, which is brash. Pieces to be bent should be dressed as nearly as possible to final sizes before bending.

The following process is applicable to pieces of approximately square cross section; for wider or flat pieces, see alternate method below. Three factors are important in this first type of wet bending. (1) a smooth rigid form without abrupt changes in curvature on the concave side of the curve; (2) a thin flexible metal strip, on the convex side, drawn tight, to reduce breakage; (3) sufficient end pressure to eliminate danger of shear on any fiber line. (See Fig. 41.) The cycle of bending and drying such rectangular members is much shortened if forming is done in a press under heat, as described below.

In another method of wet bending in solid wood members which are required in substantial quantities, such as chair backs of oblong cross section, pairs of metal forms are used. A series of steamed wet flats is placed between these forms, pressed in a hydraulic press, and the pressure maintained by bolts, as shown in Fig. 42. These clamped pairs of forms can be placed in a kiln at 150 to 180 F., the metal forms transmitting the heat rapidly to the wood members, and the pressure cycle reduced to a couple of hours, during which the bent members are dried to hold their shape with reasonable uniformity. Steam-heated forms, without supplementary bolt pressure, are also used, in which case higher temperatures may be employed, but a number of hydraulic presses are required. In general, wood curves bent by this process tend to open up somewhat on pressure release, and the design of forms should anticipate this factor. The literature of the Forest Products Laboratory at Madison, Wisconsin, should be consulted.

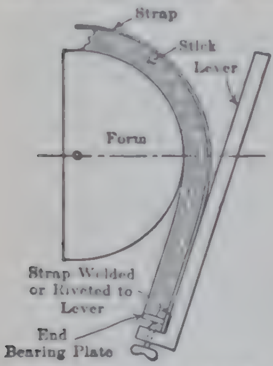

FIG. 41. Fixture for wet bending.

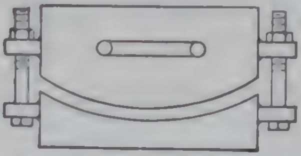

FIG. 42. Pair of metal forms for bending chair parts of solid wood.

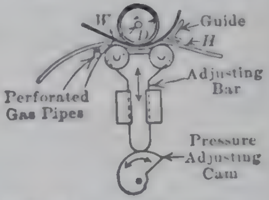

FIG. 43. Arrangement for dry bending solid wood.

DRY BENDING IN SOLID WOOD. A preferable method of bending wider and thinner pieces of solid wood is a series of three rollers, as in Fig. 43. Heat is applied to the upper roller *D*, and below the endless steel flexible conveyor belt *H*. The wood *W* is rocked back and forth until the desired degree of curvature is obtained. Temperatures may be as high as possible without charring wood surfaces. This method can be used for such items as curved slats for chair backs, and for plywood up to $^5/_{16}$ in. thick, if the adhesive is heat resistant (resin or casein). The bent pieces, both of solid wood or plywood, should be placed in skeleton curved forms until thoroughly cooled and normalized as to moisture content.

12. LAMINATED LUMBER

Solid timbers in long lengths and of substantial cross section have always been difficult to obtain since long straight logs of adequate size, without defects, are scarce. When timbers are cut from such logs they usually contain the heart section of the log, which is of questionable quality. Drying such large timbers is difficult, requiring many months, and usually results in splits, twists, and other deformations.

ADVANTAGES OF LAMINATED LUMBER. Laminated lumber fabricated from standard boards, glued together into timber sizes, while somewhat more costly, overcomes most of the difficulties enumerated above. Lumber in board form can be kiln dried without serious deterioration, glued up to any size, and such laminated products made available in a reasonable length of time and in any required quantity. End joints, adapted to anticipated loadings, can be staggered in the different layers and permit the use of relatively short boards. Narrow boards can be glued together edgewise as required. Large timbers, laminated, can be made from small trees.

Adhesives are available, stronger than the wood itself, and of maximum durability under severe weather and marine exposure. In laminated lumber constructions selected material can be used in the outer layers, where maximum stresses are encountered, and material of lower grade in the inner layers. Laminated lumber assemblies can be bent, during the gluing process, into curves for bow string trusses, cantilever arches, and other structural requirements. At points of greatest stress, such as the elbow in a cantilever arch, extra layers can be added for reinforcement. The versatility of laminated lumber is much greater than that of solid timbers.

END AND EDGE JOINTS. For column loading, square butt, or 30- to 60-degree-angle, joints may be used, properly staggered in adjacent layers. For beams subjected to bending stresses, end joints should be scarfed and lapped on a slope not steeper than twelve times the thickness of the layer. Scarfs should be cut true, closely fitted, glued with suitable adhesives, and anchored firmly to prevent slipping during pressure application. Best results are obtained when individual layers are scarfed, glued, and surfaced to uniform thickness before assembly. With adequate anchoring provisions, scarfed joints and laminae can be assembled in one operation. Scarf joints, properly made, give 80 to 90% the strength of solid lumber, and when properly staggered in the different layers, the overall strength compares favorably with solid timbers.

Edge joints are square and may or may not require pregluing and surfacing before assembly, depending on the direction of the loading.

THICKNESS TOLERANCES. All surfaces should be freshly planed before gluing, within an hour or two if possible. Thickness tolerances for softwoods are of the order of $^1/_{64}$ in., for hardwoods, $^1/_{100}$ in.

ADHESIVES. The most durable adhesive for laminated lumber is resorcinol (see Section 21, Article 10), which can be cured normally at room temperatures of 75 F and up, giving a bond as strong as the wood. Adhesives should be spread on both the mating surfaces in a joint, 5 to 7 $^1/_2$ lb of liquid resin per 100 sq ft of joint. Layers should be assembled immediately after being spread with glue, and pressure should be applied within 30 to 60 min. For maximum durability, especially with oak for ship construction, clamped assemblies should be cured in a kiln, with controlled humidity to prevent shrinking, until the most remote glue line (from the source of heat) reaches 180 to 210 F. Casein glue can be used for timbers protected from the weather, but not for marine work. Urea resin adhesives, unextended, are also used where exposure is not severe. Manufacturers of adhesives and glue should be consulted for further details.

PRESSURE. Pressure is usually applied in screw clamps (see Fig. 44), tightened by torque wrenches, indexed in foot-pounds. Wrenches should be calibrated for a standard size and type of screw in a given clamp, with compressometers, and with pressure on the lumber assembly calculated to be no less than 100 psi. The closed type of clamp with double screws (Fig. 44*b*) is preferable to the open type with one screw. Equalizers or eveners should be provided, as shown, to insure uniform pressure. Cushion pads of rubber, or other resilient material, aid in such equalization. Where headblocks 2-in. thick are used, clamps should be spaced on 15-in. centers; with $^3/_4$-in. outside layers without headblocks, the spacing should be 9 in.

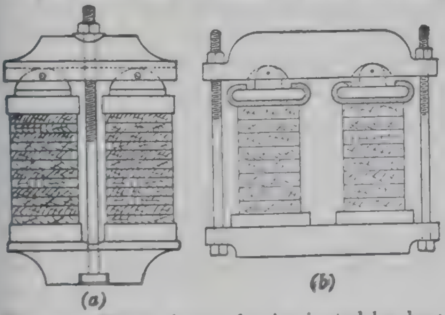

FIG. 44. Screw clamps for laminated lumber: (*a*) double C open clamp with single screw and equalizer; (*b*) closed clamp with twin screws and equalizer.

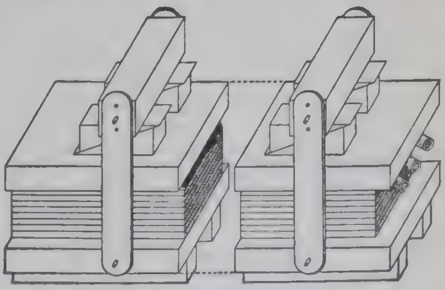

FIG. 45. Method of applying pressure for laminated lumber by flexible tubing. Wedges are used for take-up before inflating hose.

With straight members, pressure should be applied progressively from one end of the assembly to the other, or from the center simultaneously toward both ends. For curved members, the pressure should first be applied at the point of maximum curvature, and then progressively from this point toward each end. Retightening of bolts is often advisable, in 30 to 60 min, to compensate for the initial yielding of the wood under pressure.

In another method of pressure application flexible tubing, usually 2 $^1/_2$-in. (inside diameter) fire hose, is expanded; when deflated it is 4 in. wide. The technique of this method is shown in Fig. 45. The wedges are used to flatten the tube before inflation, since it is important to have a maximum of contact area after inflation. Pressure requirements within the hose increase as this contact area decreases. Alternatively, screw clamps can be used instead of wedges for flattening the tubes. This tubular pressure method has not been used extensively, but it holds considerable promise for quick and controllable clamping conditions.

CUSTOM VERSUS STOCK LAMINATING. Custom-made laminated lumber units, to a special design, have been made with entirely satisfactory results for some years. Bridge trusses and arches have given excellent service in Europe, and have been found sound after 25 to 30 years of use.

Plans are being developed by the lumber industry to establish standard sizes and grades of laminated items which can be carried as stock in lumber yards. Grade rules and tests are in process of formulation, and fabrication manuals are being prepared under the supervision of the Central Committee of Lumber Standards, in cooperation with the National Bureau of Standards.

13. WOODWORKING TOOLS

Small tools for woodworking can, in general, be used for working the plastic and phenolic materials, and also rubber. As the density of the product increases, carbide-tipped cutting edges become more and more essential for long service and smooth cutting.

FIG. 46. Forms of saw teeth.

THEORY OF CUTTING WOOD. Wood is made up of parallel fibers. Cutting lengthwise is simply peeling a layer of fibers off from those below, as with a splitting axe or carpenter's plane. In cutting across the fibers, every fiber must be severed. A knife or chisel driven forcibly across grain is the simplest form of cross cutting. Both examples represent "line" cutting without waste.

Saws divide the fibers, lengthwise or crosswise, by cutting out a swath or *kerf*. In a cross-cut kerf the fiber is first severed at both sides of the swath; the short cut fiber is then removed by a lengthwise cutting at the bottom of the kerf. In ripping a kerf with the grain, the fiber in the swath to be removed is simultaneously cross cut and peeled loose from the sides of the kerf. Cross cutting requires a knife point cut at each side of the kerf. This is made by teeth alternately high at the sides and pointed and beveled on the front. *Raker* teeth may be used to peel or split the severed fiber and remove it. Ripping requires chisel-pointed teeth, set or swaged to the width of the kerf, and with enough hook to sever the fiber with an adzing cut. It is simultaneously split loose at both sides and removed.

Saws are set, or hollow ground, to reduce friction. Surface tension or case hardening of the lumber may cause boards to pinch or close the kerf during a cut. This is one of the principal reasons for wide clearance and wide kerfs. (See Fig. 46*d*.)

With revolving *cutter heads* having knives or bits, the cut generally is lengthwise. It is not exactly a splitting cut, since only at the finish line of straight grain woods is the cut parallel with the grain. At other parts of the cut, the knives are chiseling, or adzing, and cross-cutting the grain.

SAWS have two general classifications. (1) Saws for the *primary conversion* of logs into lumber and timber. Because they are used on live or green logs, there is no danger of overheating and damaging saw temper. Such saws should be designed to cut to approximate dimensions, as subsequent shrinkage necessitates machining to final size and shape. The cutting of tough green wood requires a different tooth from the one used in the cutting of stiffer and stronger, but more brittle, dry wood. (2) Saws for the *secondary conversion* of the board after seasoning, into intermediate or final products. Saws may overheat and lose temper in dry wood, and may scorch or discolor it. Accurate, smooth cuts must be made, to produce final dimensions with maximum smoothness and minimum waste. Teeth must be shaped to cut rapidly without heating, and accurately, with minimum power requirements. The thickness of saws is designated by Stubs gage. (See p. 6-05.)

Large saws, chiefly for sawmills in primary production, can be provided with *inserted teeth* of special hard steel, mechanically locked in position, that are interchangeable and can be replaced to compensate for excessive wear due to grinding.

Carbide-tipped teeth are also used on smaller saws in secondary production, brazed electronically to the standard steel blade. Carbide-tipped teeth give long cutting service, on densified wood as well as on casein and resin glue joints, where abrasive characteristics may be encountered. Carbide-tipped teeth have rather blunt cutting edges, cannot be sharpened in the regular way, and require high speeds for smooth cutting.

The two general classifications of primary and secondary conversion may be still further subdivided as below. Figure 46 shows the various forms of saw teeth.

Saws for Primary Production (converting green logs into timber and lumber):
- Circular saws.
  - Solid disks.
    - Parallel-to-grain or rip cut (Fig. 46*a*).
    - Perpendicular-to-grain or cross cut (Fig. 46*b*).
  - Inserted teeth.
  - Shingle saws, thin edges with thick centers.
- Band saws, continuous or endless (Fig. 46*f*).
  - Parallel-to-grain for cutting logs into lumber and timber.
  - Perpendicular-to-grain, drag saws for log lengths.
- Band saws, reciprocating, mostly gang resaws.
- Special-purpose saws.
  - Cylindrical, for cooperage stock (Fig. 46*h*).
  - Concave.

Saws for Secondary Production (converting dry boards into diversified wood products):
- Circular saws.
  - Ripping (Fig. 46*a*).
  - Cross-cutting (Fig. 46*b*).
  - Combination (Fig. 46*c*).
  - Special-purpose (Fig. 46*e*).
- Band saws, continuous or endless.
  - Ripping or resawing, wide (Fig. 46*f*).
  - Curved and special shape, narrow (Fig. 46*g*).
- Band saws, reciprocating.
  - Jig and scroll saws.
- Special-purpose saws.
  - Dadoing (Fig. 46*e*).
  - Tenoning and mortising.

KNIVES AND CUTTERS. The function of a knife or cutter on a planer, molder, or shaper is to reduce the surface or edge of a part to the desired shape and dimensions without marks or scratches, and with a smoothness that can be finished. A roughly sawed surface or edge requires more subsequent machining than one smoothly sawed. Close correlation between the roughness of the saw cut and the depth of the planer cut is necessary. Often, as in jointing plywood cores, a saw can be made to cut smooth enough to eliminate a separate jointing operation. A slightly rough cut is considered better for gluing than one with a very smooth edge.

Following are the basic machines using knives and cutters. (1) Planers or jointers using straight cutting edges to produce plane or level surfaces. They cut continuously along a straight face, not on the side, and parallel or nearly parallel to the grain. (2) Molders or stickers, which are, in effect, multiple planers, usually designed to cut straight or irregular surfaces on all four sides of a piece simultaneously. Cutting may be with either face or side of the knife, but substantially parallel with the grain. (3) Shapers, which are particularly designed to produce irregular and curved shapes or edges both in vertical and horizontal planes. They use a variety of solid, sectional, and laminated cutters, often cutting at an abrupt angle to the grain.

On relatively large diameter wheels, the method of attachment of knives and cutters for planers, molders, and shapers determines the classification. This involves both the provision made for knife attachment, and the corresponding design of head to which knives are attached. Rigid mounting is imperative because of high operating speeds, strong centrifugal forces, and the deep cuts often required.

Knives are distinguished, in general, by thickness. (1) *Thick knives*, usually comprising a tempered steel face and cutting edge, welded to a softer steel back used for clamping. Narrow knives of the chisel type may be entirely of tool steel, tempered principally at the cutting edge. (2) *Thin knives* which require clamp bars and plates, or attachments. Such tool-steel knives seldom are recessed for attachment. They require stiffener bars to provide rigidity and firmness. A knife that chatters will not cut smoothly.

Cutter heads, knives, and router bits can be provided with *tungsten carbide* cutting edges that give long service against very hard species, impregnated, fireproofed, and densified woods, and also resin bonded plywood. The cutting edges of these carbide tips, brazed electronically to a standard steel backing, are rather blunt and cannot be readily sharpened or ground to shape. High linear cutting speeds are necessary for smooth cutting. Solid tungsten carbide cutter heads or knives are seldom practicable, since this alloy lacks the toughness and strength of the standard steels under severe torsional and tension stresses.

Knives and cutters may be classified by machines and by thickness, as follows:

- **Planers and Jointers** (for cutting straight surfaces, single and double, parallel to wood grain):
  - *Thick rigid knives*, parallel to axis of head (Fig. 47*a*).
    - Square heads.
      - Two-knife (Fig. 48*a*).
      - Four-knife (Fig. 48*c*).
    - Face clamping.
      - Oval holes in knife with bolts adjustable in slotted head (Figs. 47*b*, 48*c*).
      - Slotted holes in knife, with tapped holes in head (Figs. 47*a*, 48*a*).
      - Ribbed-surface knives for rigid clamping (Fig. 47*c*).
    - Round heads.
      - Clamped with countersunk bolt heads.
      - Internal bolt clamping devices.
  - *Thin Knives*, semiflexible, requiring support and clamp bars (Fig. 47*d*).
    - Knives parallel to axis of head.
      - External clamp bars and bolts.
        - Square heads (Fig. 48*d*).
        - Round heads (Fig. 48*g*).
      - Internal clamp bars and bolts (Fig. 48*e*).
      - Wedge and taper clamps (Fig. 48*f*).
    - Knives spiral to axis of head.
      - External clamp bars and bolts.
      - Internal clamp bars and bolts.

- **Molders and Stickers** (for cutting multiple straight and irregular surfaces parallel to wood grain [Figs. 50*a*, 50*b*, 50*c*]):
  - *Thick rigid knives* (straight, not spiral).
    - Angular heads.
      - Two-knife (Fig. 48*a*).
      - Three-knife (Fig. 48*b*).
      - Four-knife (Fig. 48*c*).
    - Face clamping.
      - Tapped holes in head (Fig. 48*a*).
      - Bolt slots in head (Figs. 48*b*, 48*c*).
      - Ribbed-surface knives for rigid clamping (Fig. 47*c*).
    - Edge clamping.
      - External bolts (Figs. 49*a*, 49*b*).
      - Vise or jaw clamps (Figs. 49*c*, 49*d*).
      - Slotted bolts with adjustable cutting angles (Fig. 49*c*).
    - Round heads.
      - Clamped with countersunk bolt heads.
      - Internal bolt clamping device.
      - Wedge and taper clamps (Fig. 49*f*).
  - *Thin knives*, semiflexible; requiring support and clamp bars.
    - Knives, parallel to axis of head.
      - External clamp plates and bolts (Fig. 48*d*).
      - Internal clamp plates and bolts (Fig. 48*e*).
      - Wedge and taper clamps (Fig. 48*f*).
    - Knives spiral to axis of head.
      - External clamp plates and bolts.
      - Internal clamp plates and bolts.

- **Shapers** (for cutting irregular surfaces in two planes and frequently at abrupt angle to wood grain):
  - *Knife blades clamped to head.*
    - Face clamped to head.
      - Slotted hole, tapped hole in head (Fig. 48*a*).
      - Slotted knife and bolt in head (Figs. 48*b*, 48*c*).
    - Edge clamped.
      - External bolts (Figs. 49*a*, 49*b*).
      - Vise or jaw clamps (Figs. 49*d*, 49*e*).
      - Slotted bolts with adjustable cutting angles (Fig. 49*c*).
    - Clamped with pressure bars or plates (thin knives).
      - External clamped with countersunk bolt heads.
      - Internal clamped.
      - Wedge and taper clamps.
    - Thin knives of slightly irregular shapes (Figs. 48*a*, 48*b*, 48*c*).
  - *Solid knife heads mounted on arbor.*
    - Thick knives of a wide range of shapes (Figs. 48*d*, 48*e*).

BORING TOOLS. The principle underlying a boring tool or bit is similar to that of a shaper tool, except that the boring tool advances into the wood. Mechanical means must be provided for this movement, as well as for the removal of chips from the enclosing hole along the spiral shank of the bit. The two basic types of boring tools are these: (1) Boring into *side wood*, where the bit requires side spurs to sever the wood fibers on the circumference of the hole, before the cutting and lifting edge of the bit separates the chips along the fiber line. (2) Boring into *end wood*, where the bit shears off the fibers as it advances, the cutting of the circumference being merely a separation of the fibers. (See Fig. 51.)

Bits. Figure 52 shows four main types of bits. The *double-spur* bit is a general utility tool, usually made with a single-thread screw point. The *extension lip* bit usually has a double-thread point. It is used to produce smoother holes, with less liability to split hard wood. Both types are used to bore holes in side wood. The *taper head drill* is designed for boring end wood. It may be used for side wood if a rough hole is not objectionable. The *spur machine drill* is a modification of the taper head drill. It has spurs and a brad point, to adapt it to better boring service in side wood. It is used in gang boring where holes may be at various angles to the grain.

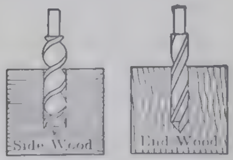

FIG. 51. Boring into side and end wood.

The kind of spiral groove or twist for chip removal depends on bit size, depth of hole, and direction of grain. Figure 53 shows the more important types. The *double twists* are usual for medium and large regular boring; left-hand is standard for a bit turning clockwise. Some gang boring machines require right-hand twist bits, rotating counterclockwise. The *solid center twist*, with a round stem or shank in the center, is used for small bits. The *ship auger twist* has the largest body of metal on the edges, the center being used for more adequate chip removal. It is most suitable for deep boring in large timbers. The *drill* *twist* has a much more rapidly rising spiral than others, its function being the removal of smaller end wood cuttings, rather than side wood chips. It is ground so that the margin is wide enough to resist wear, thus maintaining the diameter.

Figure 54 shows bits for boring concentric holes, sometimes called counterbores. The countersink *a* is for flat-head screws, while recessing, as for washers or bolt heads, is done with one of the forms of counterbore of which *b* and *c* are examples. Many other combinations may be made for both side and end wood.

Large-diameter shallow holes do not require bits with spiral shanks, as chips seldom clog. Figure 55 shows two types, *a* for solid wood and *b*, with saw teeth on the circumference, for plywood. Both have brad points.

Figure 56 shows *plug cutters* with ejector plungers, one of which has inserted high-speed steel teeth for abrasive plywood adhesives, as casein.

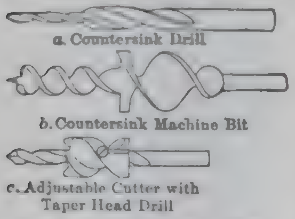
FIG. 55. Bits for large diameter shallow holes.



a. Countersink Drill

b. Countersink Machine Bit

c. Adjustable Cutter with Taper Head Drill

FIG. 54. Counterbore bits.

Router bits (Fig. 57), while similar in appearance to boring tools, have different functions. A router is chiefly used to cut recessed grooves or to cut out, by means of grooves, regular or irregular outlines. A router bit has a cutting lip throughout its length to produce smooth-edge grooves. It rotates at much greater speeds than a boring bit. The function of side cutting is much more important than end cutting. The advance cut of a spur is not needed, and the fluted clearance slot, for chip removal, may be straight instead of spiral. Router bits may be designed for various shapes, like T slots, ogee grooves, and the like. In this form they may resemble shaper knives and heads.

Router bits, for densified types of wood and plywood, are frequently provided with *carbide-tipped* cutting edges, as shown in Fig. 58. Such router bits give long service under severe operating conditions, but must be carefully designed with adequate reinforcing backings of tough standard steels to withstand excessive torsional stresses. Carbide-tipped cutting edges are relatively blunt, require high speeds for smooth cutting, and are difficult to sharpen.

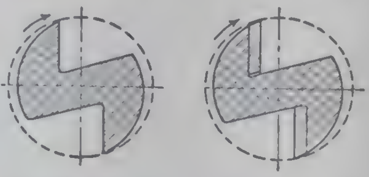

FIG. 58. Sections through router bits without and with carbide-tipped cutting edges on each flute.

MORTISING TOOLS (Fig. 59) are duplex boring and chisel cutting tools. A central standard bit bores a round hole, and, surrounding the bit, a square four-side chisel removes or broaches out the round fillet corners. Chips from both cuts are lifted out by the spiral shank of the bit and discharged through clearance slots in the square chisel shank (one for soft wood, two for hardwood). The slots are located above the wood surface at maximum cutting depth. Chisel points are longer at the corner than at the center, to insure a shearing cut in removing corner fillets. Oblong holes, up to 1 $^1/_2$ by 1 dimension ratios, can be made with a rectangular oblong chisel, as in Fig. 59*b*. If a 2 by 1 ratio is required, and the shape of hole is concealed by shoulders on the tenon, the result can be obtained at a single stroke by the hollow chisel (Fig. 59*c*). The cutting edges of the chisel are arranged for shear cuts on all four sides. Otherwise, oblong holes are made by multiple strokes of a square mortising tool. Proper clearances must be provided between internal bits and external chisels to avoid friction, heating and burning the wood. In setting mortising tools, the chisel is set first, and then the bit, with the bit cutting lips extending a little beyond the extreme cutting tips of the chisel. Mortising tools are not suited for cutting end wood.

b. Oblong Hollow Chisel

c. Oblong Bar Hollow Chisel

FIG. 59. Mortising tools.

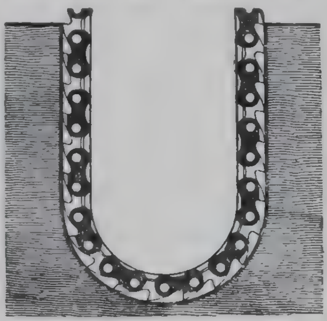

FIG. 60. Mortising chain with saw teeth on outer periphery.

Mortising chains are available for oblong holes, being a series of cutters attached to an endless chain. They are chain saws in principle (Fig. 60), not boring tools, but produce a similar result. The hole has a rough edge, but may be satisfactory for such products as mortise-and-tenon doors, although the joint cannot be very snug.

14. MACHINE TOOLS FOR WOOD

SAW MACHINES. The five principal types of saw machines are: (1) *rip-saws*, circular cutting; (2) *cross-cut saws*, circular cutting; (3) *variety saw tables*, circular cutting; (4) *band saws*, continuous band cutting; (5) *jig* and *scroll saws*, reciprocating band cutting. In many machines, rip, cross-cut, or combination-tooth saw disks may be used interchangeably, while some are single-purpose machines. See p. 25-34 for saw disk types and teeth.

Saw cuts are required on a variety of machines, where the saw cut is auxiliary to the general purpose of the machine. Examples are double-end tenoners, dado heads, or grooving cuts on molders, trim cuts on veneer jointers, or a cut-off on a dowel machine. In general, the best cutting speed for either a circular saw or band saw is approximately 10,000 ft per min.

Rip Saws. Machines designed exclusively for ripping are of two main classes. (1) Single or multiple ripping of full length boards, often the preliminary dimensioning operation in a planing mill, and sometimes in a furniture factory. In gang setups, to avoid a winding cut, saws must be of equal diameter and approximately the same degree of set and sharpness. Saws usually are mounted on the lower arbor, with pressure or feed rollers above. (2) Single ripping of cross-cut stock (often called straight-line rip saws). The saw usually is mounted above, with an endless feed chain below. Such saws often give a sufficiently straight and true edge for gluing. Arbors are sometimes below the work, the saws extending upward between a divided feed chain, above which are mounted idling pressure or feed rollers.

Cross-cutting saws (also called stock-cutting saws) may be of these types. (1) Swing saw (an older type) hung from the ceiling and swinging into the work on an arc. (2) Clip saw, swinging from below, with the motor drive pulley concentric with the pivot. (3) Saws on sliding ways, or other mechanical device, to move them horizontally into the work and out. Cross cutting usually is the first dimensioning operation in a furniture factory.

Variety saw tables may be equipped interchangeably with rip, cross-cut, or combination (rip and cross-cut) saw disks, depending on the work. For grooving or tenoning, dado heads or *wobble saws* may be used. Wobble saws are angle mounted, with wedge-shaped collars, between two perpendicular saws for slotting or rabbeting. Variety saw tables generally are equipped with side gages, back gages, and angle adjustments for miter sawing. For angle cutting, the table may tilt or the arbor may be pivoted. In size, they range from small bench saws up to floor machines. Speed of floor units usually is 3400 to 3600 rpm, requiring 5 hp.

Since all circular saws cut against the feed, the operator should take great care to avoid dangerous "kick backs." Most modern saws have mechanical devices to protect against both kick backs and hand hazards from the saw disks.

Band Saws. Resaws for such operations as ripping special thicknesses usually are about 6 in. wide, with heavy corrugated feed rollers on vertical shafts. Regular band saws may be equipped with a variety of blades, seldom wider than 1 in. for straight work, and down to $^1/_4$ in. for curved work. Band saw wheels range from 30 to 36 in. in diameter, with direct-connected motor on the lower wheel. Band saw throats take work up to 36 in. wide by 18 in. thick. Motors are 3 to 7 $^1/_2$ hp; wheel speeds are 600 to 1200 rpm. Small bench models also are made.

Jig and scroll saws are used chiefly for cut-outs that cannot be made on band saws, and are much less costly than band saws for small shops. The development of the high-speed router, producing smoother edges, has greatly lessened the utility of the jig saw.

PLANING MACHINES. The underlying principles of cutting wood surfaces in the planer also are used in the jointer, molder (sticker), and flooring machine. The following explanation of these principles in the planer applies also to these other types of machines. See p. 25-37 for the forms, shapes, and methods of attachment of knives.

Cutting Mechanism. Figure 61 shows a section of a typical planer cutting mechanism. The cutting head revolves against the infeed of the stock, and the grooved *infeed rolls* should be powerful enough to withstand the double load of feeding stock and holding it against the action of the cutters. Infeed rolls often are made in sections to bear more uniformly on thick and thin stock. Large single surfacers and all double surfacers have two pairs of infeed rolls. Pressure of the feed rolls tends to straighten crooked lumber, but the ordinary planer cannot be relied upon to remove wind and warp entirely. Special types are used for this purpose. (See p. 25-42.) The *chip breaker* prevents lifting and tearing of the grain, and reduces all chips to a size that will not clog the cutting head or be difficult to move as shavings in the dust collector system. The steel-tipped chip-breaker shoes ride the top surface of the incoming lumber, and are substantially concentric with the cutter head. They are suspended from a sturdy cross bar, as a heavy cut places a severe strain on chip-breaker mechanism. The smooth *outfeed roll* and the *pressure bar* require exact adjustment to the final planed thickness. They must be rigid enough to prevent any chatter or end clipping in the board during the planer cut.

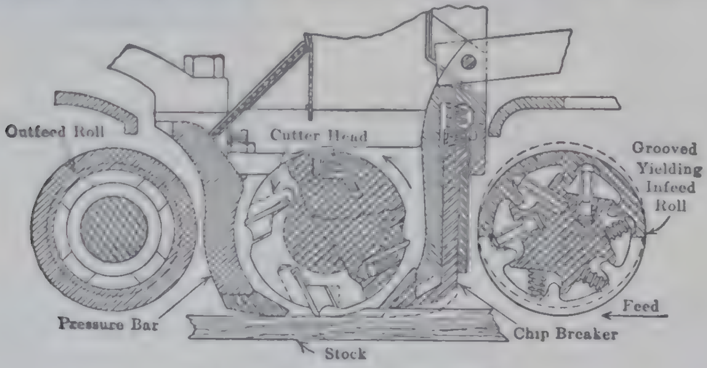

Fig. 61. Planer cutting mechanism.

The *cutter head* in Fig. 61 is of the round type with four thin knives, clamped in slots. While it is possible to set the several knives in approximate alignment, it is necessary to joint or grind all knives, at operating speed, to a true cutting line, after they have been set and clamped in the head. This is done preferably with a special motor-driven traveling grinder mounted over the main bearings of the planer. In some cases (as an enclosed lower knife head), the head is partially or wholly removed, with the knives clamped in place and ground in that position.

Planer cutting circles usually are about 6 in. in diameter but vary with the different makers and shaft lengths. Since the standard speed of planer shafts usually is 3600 rpm (7200 when a frequency changer is used), it is important that they be in perfect mechanical and static balance, requiring careful attention to the individual weights of knives and clamping devices. One of the most difficult problems of planer design is to overcome shaft whip or deflection at high speeds, especially in the wider machines, tending to produce uneven thicknesses and rough planing.

Proper *cutting angles* are important. They vary with the species and dryness of the wood. Table 10 gives their dimensions.

Table 10. Cutting Angles and Knife Cuts per Inch for Planers and Similar Machines

Above figures apply to stock 1/2 in. thick or thicker. For stock less than 1/2 in. thick, increase the knife cuts per inch 10–50%.

To prevent tearing out grain on dry stock, decrease the cutting angle or increase the knife cuts per inch.

To prevent roughing up or raising the grain on wet or green stock, increase the cutting angle and decrease the knife cuts per inch.

Knife Cuts per Inch. A definite relation exists between the rate of feed, the peripheral speed of the cutter and the number of knives in the shaft. At best, any planer cut is a series of miniature waves in the planed surface, the degree of smoothness depending on the shortness of the individual waves. This relation is clearly indicated in Table 11.

Table 11. Knife Cuts per Inch with 3500 Rpm Spindle Speed

(Rpm × Number of knives)/(Ft per min × 12) = Cuts per inch

Types of Planers. The principal types of planing machines are (1) general-purpose planers, (2) cabinet planers, for high quality work; (3) mill-type planers, for surfacing full length boards.

General-purpose planers, ordinarily used in so-called planing mills and job shops, have a bed (thickness) adjustment in vertical ways by means of two geared screws. With this construction a slight rocking motion is unavoidable, when stock is entering the infeed or leaving the outfeed rolls, which may be unimportant in many rough planing operations that do not require precision. Since the average cost of this type is less than that of the cabinet planer, it usually lacks the better attachments and more accurate adjustments of the latter.

Cabinet planers owe much of their precision to bed adjustment by motor-actuated sliding wedges, giving both accuracy and rigidity. The range of adjustment is less than that of the general-purpose planers, but tendency to rock is entirely eliminated. In cabinet planer design, the point of the chip breaker is placed as close as possible to the actual point of cutting, to reduce the size of chips and lessen the tendency to tear out ahead of the cut. The chip breaker usually is of sectional or flexible construction, to ride equally well on thick, thin, and rough spots in the stock. High-grade planer work demands a large number of knife cuts per inch, which is obtainable either by increasing the number of knives (up to six, rarely more) in the head or stepping up the speed of the shaft, a point on which opinion is divided. Straight knives generally are used, but spiral knives occasionally are used to distribute the load and reduce pull-outs at the back end of the stock.

Motor equipment for planers varies with the service. Standard power ratings for single surface cabinet planers are:

Planer width, in.	26	30	36	40	44	50	60	64
Horsepower	10–15	15–20	20–25	20–25	20–25	20–25	25–30	25–30

Feed mechanism may be driven direct from the motor on the cutter shaft by belt to a constant diameter pulley, or by a variable-speed V-belt drive (between expandable flanged pulleys), thus permitting an adjustment of the feed with relation to the speed of the cutter head. When frequency changers are used on the cutter heads it is an advantage to have separate multiple-speed constant torque motors on the feeding mechanisms.

Speeds usually are up to 60 ft per min, occasionally 100 ft per min, with considerably slower speeds for exacting work.

Production cabinet planers often are fitted with *hopper feed*, the infeed bed or table being equipped with an endless rubber-faced conveyor chain, with slats or side rollers for random lengths. Hopper feeds usually are set on an angle to feed pieces diagonally.

Cabinet planers are made for double surfacing, the lower cutter shaft then being arranged to be pulled out for adjustment and jointing. Double surfacing planers usually are built from 30 to 44 in. wide with larger power requirements than single surfaces.

Special feeding mechanisms are required when the warp and wind in the lumber are beyond the capacity of the infeed rolls to control sufficiently by pressure. These mechanisms, on a single surfacer, called a *facing planer*, have an overhead flexible fingered infeed chain, and produce a true surface on the underside of the board against the cutter head. Two or more surfacings may be required for especially crooked lumber. The rough side is surfaced in a subsequent operation, in the same facing planer or in a standard cabinet planer.

A combination double surfacer, called the *Straitoplane*, has this flexible fingered infeed chain for the lower cutter head to produce an initial true surface on the underside of the board, followed by a standard upper planer head, rigid bed, and outfeed roll for the subsequent facing of the upper side of the board. The second cut can be adjusted for accurate thickness. This machine operates efficiently on stock as short as 10 in., and is particularly adapted to furniture work where most pieces are relatively small. Each cutter head is driven by a 15-hp motor at 3500 rpm. A 5-hp, 2-speed motor drives the feed. The machine is standard at 36 in. wide. Feeds up to 60 ft per min are practicable.

Mill planers are designed primarily for use with full-length lumber. They have been developed, and are used principally, on the Pacific Coast. Feed mechanism comprises endless chains with cross slats of ribbed cast iron, giving a more powerful and positive feed than is possible with rolls, but lacking somewhat in accuracy of cut. The cutter head is above, with the adjustments of a cabinet planer. Bed adjustment is of the sliding wedge type. Capacity is stock 8 in. thick, 30 to 36 in. wide. Feeds of 100 ft per min are practicable.

Jointers are classified as:

Standard Jointers. The cutting mechanism of the jointer is quite similar to that of the planer with a cutter head below the bed, but the feed mechanism is omitted, since edged jointing is the predominant function of the jointer. Jointers are provided with a high *fence* (side gage) to permit them both to square and to true the edge. Portable bench jointers are made and extensively used in preference to the hand plane. Jointers seldom are made over 16 in. wide, and sometimes are hand fed to take the wind out of dimension stock. This is particularly important in producing a true bed surface for molder or sticker work.

Lumber Jointer. The continuous feed lumber jointer, often called a *glue jointer*, has an automatic return feed for edge jointing strips for plywood core stock. This is a duplex or return cycle machine, with an endless feed chain in the center, mounted on vertical shafts. The two cutter heads revolve in opposite directions. A board to be jointed on both edges is placed edgewise at the infeed end against the feed chain, jointed on the lower edge, passed over a tipping mechanism that turns the unjointed edge down and into the reverse feed track. The board travels back to the infeed end, moved by the opposite side of the feed chain, passing over the second cutter head. This machine is suitable only for use on ripped stock, as the cut is insufficient for rough or wany-edge stock, and it will not produce uniform width.

Veneer jointers are highly specialized jointing machines. They operate on a flat *package* of sheets of veneer, aggregating 2 in. thick, which must be clamped firmly during the entire cutting period. The cutter head, usually mounted on a vertical shaft, carries as many as twelve knives to give the smooth edge necessary for matching high-grade veneer faces. In some machines the clamped package travels past the revolving knife head. In others, the clamp is stationary, and the head travels.

Molders or stickers are essentially four-sided planers, with two horizontal and two vertical shaft cutter heads, usually square four-side heads (see Fig. 48*c*). The feed may be by pressure rolls against a rigid bed or by endless feed chain below. Cuts frequently made are irregular and curved faces on moldings. Cutter heads, so far as possible, have chip breakers and the other auxiliary devices of the planer. Since all cutter shafts are short, knives and cutter heads are bolted on ends of shafts, and it is possible to use high speeds with frequency changers, up to 7200 rpm. Fewer knives are required at high speeds to give the same number of knife cuts per inch. This is a distinct advantage in grinding special knives as most molder heads are four sided, and the uniform setting of four irregularly shaped knives is most difficult. It is usual to operate a molder head at high speed with two opposed knives of the same shape and a correspondingly greater rate of feed. For long runs on standard shapes, solid cutter heads are often used, with knives jointed in a profiling machine.

Modern molders have brackets for *cope heads*, which make re-entrant cuts that are not possible with regular heads. They also often supplement the regular heads by making deep cuts that would require impractical or very costly knives. Molders are close coupled and compact, usually with individual motors for each head and for the feed. A popular size takes stock up to 4 by 4 in., but they are made up to 16 by 6 in. for heavy timbers.

Flooring machines are specially designed molders, the two vertical shafts making the tongue and groove, while the lower horizontal head makes the flooring face, and the upper head cuts the hollow back. A steel lettering wheel often grades and trademarks the back as it leaves the machine. Flooring machines are designed to operate on full-length lumber and at high speeds.

THE SHAPER is one of the oldest types of machines. It still is important in woodworking, although many of its functions have been absorbed by more specialized machines. It is a versatile machine for small shops, as it is more easily set up for short runs than many of the specialized machines that are more efficient for long runs.

The shaper consists essentially of a large flat metal table with a vertical spindle, driven from below, extending up through the center of the table. Revolving cutter heads, mounted on the end of the spindle, accommodate a variety of knives for a wide range of cuts. (See Shaper Knives, p. 25-36.) Solid heads may be mounted for long runs. A job to which a shaper is best adapted is the shaping of the edges of table tops, especially those of other than rectangular form. The table top blank is firmly mounted, by two or more points, on a jig of the desired shape. A spindle collar is mounted at the machine table level, above which the knives are set and clamped for the required shape, ogee or otherwise. The operator revolves the combined jig and blank, holding it snug against the collar for one complete revolution of the jig, and thus producing the ogee edge around the periphery. Shaper knives cut with the grain rather than against it, as far as possible. Slow feeds are necessary when cutting at right angles to the grain. Blanks may be reversed on the jig to help this condition.

The shaper is especially useful in re-entrant curves, octagons, and other odd contours not suited to machines designed for rectilinear or circular cutting. Small molding, flutings, both straight and curved, and many edge and end cuts can be made on a shaper.

Shapers frequently are equipped with two spindles, usually rotating in opposite directions. All cuts around an irregular table top can then be made in a direction favorable to the grain, and no cuts have to "dig into the grain," leaving a rough and torn edge. The jig, with mounted work, is moved from spindle to spindle according to grain requirements. Automatic shapers are equipped with mechanically operated jigs or revolving tables to which blanks are held with pneumatic clamps. These are suited only to long production runs.

THE ROUTER is a relatively modern machine, achieving its effectiveness with the development of high spindle speeds. It is somewhat the reverse of the shaper, and usually is designed for considerably lighter cuts. The cutting head is above the table, which is provided with an upwardly projecting, jig-guiding round plug of the same diameter as, and directly under, the cutter. The cutter head carries a router bit (see p. 25-38) rotating at speeds of 20,000 rpm or higher. The table may be moved up to the bit, or the bit lowered into the work. The router is admirably adapted to cutting out (with grooved cuts) grills or irregular shapes. It works much better and more quickly than jig saws. Router bits may have shoulders for shaping the edges of cut-outs, or T heads for slotting. Straight cuts on narrow strips can be made by clamping suitable gages to the table. A straight gage, through or near the bit center, permits shaping of straight-edge table tops and similar work.

Router motors, both electric and pneumatic, must be very accurately balanced for excessively high speeds. Brakes are provided to slow down the bits, which otherwise would require a long time to come to rest. Blowers, directed to the exact point of cut, are standard equipment to prevent chips and shaving from clogging the cut and heating the bits. Some routers are equipped with tilting tables. In these the bit is lowered into the work. Motors are 1 to 5 hp for heavy duty. Spindle speeds often are stepped up by V belts.

Portable hand routers are built to operate electrically and pneumatically. Electric machines operate at 10,000 rpm maximum; pneumatic, at 60,000 rpm maximum.

CARVING MACHINES are of two main types, single and multiple.

Single carvers may be rigidly mounted on a floor standard, the work being moved free-hand by the operator. The single carver also is available in the balanced suspension type, hung much like a dentist's drill. The work is held stationary and the drill moved over the pattern by the operator. In both types the mechanism consists of a small high-speed motor with a small spur drill mounted directly on the motor shaft. Single carvers are used for a certain amount of undercutting. Final retouching usually is by hand.

Multiple carvers may carry as many as twenty-four blanks, all to be roughed out uniformly from a master pattern or model, usually of metal. The spur cutters are moved in unison by link levers that are fixed in their relation to each other. Cutters usually are belt driven from one or more motors. Individual motors can be used for extra heavy cuts. Such machines can only rough out the carvings, but their efficiency consists in removing all surplus wood, even on deeply recessed carvings, leaving a minimum of hand carving of finer lines and undercuts. This type of machine has greatly extended the use of carving on classical furniture at very reasonable cost. But one operator is required, who guides the blank cutter over the pattern, carefully watching the direction of the cut to avoid tearing the wood. The hand finishing work reproduces the character of hand carving. This process is displacing pressed and overlaid imitation carved work.

BORING MACHINES range over a wide variety of woodworking machines, from a single bit held in clutch jaws on the end of a motor shaft, to gang or multiple machines in various arrangements, sometimes equipped for as many as thirty bits. Some bore only vertical holes, others bore horizontally, and still others bore at various angles, depending on the complexity of the work. The maximum number of individual bits seldom exceeds thirty, but special machines have been made for a large number of boring problems. The literature of the industry should be consulted for more specific information.

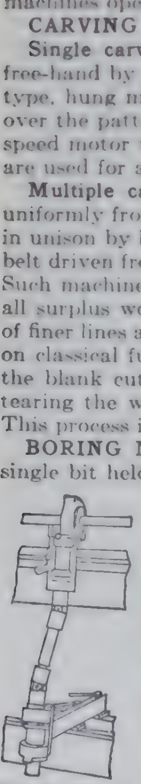

Fig. 62. Boring mill spindle with universal joint.

Vertical multiple borers carry a series of fixed or adjustably positioned spindles, usually arranged in approximately single or double vertical ranks, with a clamp-equipped work table moving up the bits. Spindles may be fixed or *rigid*, i.e., maintain a vertical alignment with the splined drive shaft above, or *adjustable* to points at quite a horizontal distance from the plane of the drive shaft, by a telescopic universal joint (see Fig. 62).

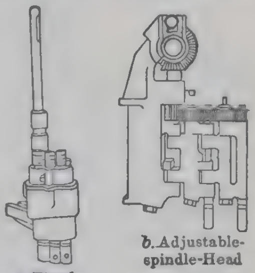
Horizontal multiple borers differ from vertical borers principally in boring a series of horizontal holes, having a work table that moves in and out. They are used mostly for end boring. Universal-joint spindles are not generally adaptable to horizontal boring. However, adjustable multiple or cluster boring heads, to which bits are fixed in position in the head, are available.

Cluster vertical borers (not made in horizontal types) have universal-joint spindles, adjustable over rectangular or circular areas up to 40 in. in diameter, with many combinations of bits that may be attached. Motors are above, and operate the bits through gear trains which terminate in fixed sockets for spindle connections. The universal-joint spindles permit a wide range of adjustment of bits in any horizontal direction within operating limit.

Multiple boring heads are principally (1) fixed cluster (Fig. 63*a*); (2) adjustable multi-spindle (Fig. 63*b*). Many other types of heads are made, for use in both vertical and horizontal boring machines.

Standard spindle speeds range from about 1000 to 2000 rpm, varying principally with size of hole, hardness of the wood, and rate of feed.

LATHES differ widely in basic principles, developing by degrees from the plain hand lathe, which is one of the oldest woodworking machines and suited to a wide range of individual work. The principle of the high-speed cutter head has been borrowed from the shaper and adapted to many lathe cuts, especially for duplicating work. Patterns and cams have been adapted from such machines as the carver, and other devices, for various other types of cut. Only the principal types are described below.



b. Adjustable-spindle-Head

a. Fixed Center Cluster

FIG. 63. Multiple boring heads.

The copying lathe works entirely from a model or pattern of the exact shape required. It can be used for gun stocks, axe handles, shoe lasts, parts of period furniture, etc. The blank to be turned and the pattern are mounted on slowly rotating gear-driven centers. The cutting member is either a high-speed revolving cutter head or occasionally a heavy saw. Its movement is controlled by a tracing pin, or roller, which traverses all portions of the pattern, producing an exact duplicate. Usually the cutter moves along the length of the blank, but in axe handle lathes the frame, with centers, blank and pattern, moves past the cutter head.

Back knife lathes first turn the blank to a rough round by a ring or die with inside cutting edges, supported on a traveling carriage. The die is moved out of the way, over the dead center, for the turning operation. The long back knife is so set, milled to such a shape, that when in an angling cutting position against the blank, it gradually cuts in, and is stopped when the final turning is of correct size and contour. The back knife never is the exact reverse of the turning, but a mechanically developed extension of it.

The shaping lathe is an exceedingly versatile machine, turning rounds and polygonal sections in almost every conceivable combination. Both lathe centers are "alive," and oscillate slowly into and out of the cutting zone, under the operator's control. Cutter knives, similar to a series of shaper heads on a single shaft, are mounted on a cutter spindle or arbor in the rear, and revolve at high speed. All knives are mounted on the arbor, whether for square, round, or hexagon cuts. As a general rule, where squares and rounds are on one turning, flat surfaces are cut first, the lathe centers turning through a small arc, and keeping the work tangential to the revolving cutters by a cam. The piece to be turned is withdrawn from the cutters, turned through approximately a 90-degree angle (for a square), and the next flat surface is cut. The angle of movement controls the number of sides for squares, hexagons, octagons, etc. After the flats are completed, the rounds are turned, with lathe centers slowly and uniformly rotating. Various modifications may be made in this procedure for complicated types of turning or shaping pieces other than turnings. The setup of the cutter head may be so complex as to demand long production runs for good economy.

Many different types of lathes are built in addition to the major types described above. The literature of the industry should be consulted for detailed information.

MORTISING MACHINES may be classified as (1) hollow chisel mortisers; (2) chain saw mortisers; (3) oscillating bit mortisers.

Hollow chisel mortisers usually provide a vertical movement of the tool into the work. Horizontal types also are available. The tool (see p. 25-39) is attached directly to the motor, the rotating bit being motor driven. The surrounding nonturning chisel is mounted in the chisel carriage on the motor frame, and both are forced together into the work. The tables are equipped with clamps, adjustments, and multiple end-gages, as several mortises may be made in the same piece. Tool strokes may be arranged automatically to repeat cuts for oblong holes, up to about 50 per minute. Horizontal movement of the table also may be automatic for a series of mortises. Motor sizes range up to 4 hp at 3600 rpm. Multiple hollow chisel mortisers always are horizontal stroke, limited to six heads, with a minimum of 4 in. center spacing, and a maximum spacing of 72 in. between outer heads.

Chain saw mortisers operate with cutting teeth mounted on the outside periphery of a link chain. (See Fig. 60.) The minimum size of hole is $^{3}/_{16}$ by $^{3}/_{4}$ in.; the maximum may be $1\,^{1}/_{2}$ by 4 in. Longer mortises may be cut at one stroke by using a double roll bar, or by successive cuts. The table moves the work up into the chain cutters. Sprocket motors usually are 3600 rpm, giving the following approximate chain-cutting speeds:

No. of sprocket teeth	5	7	9
Chain speed, ft per min	1330	1930	2400

Multiple-chain saw mortisers are available up to 8 heads, which may be stationary, or adjustable in and out as well as sideways. Chain saw mortisers are not made in horizontal types.

Oscillating bit mortisers make round-end holes, whose depth is limited by the size of the router-type bit. The bit oscillates between stops set for the desired lengths. Oscillations seldom should exceed 200 per min; bit speeds are up to 7200 rpm. Oscillating motor usually is 1 hp; bit motors may be 4 hp. Air clamps hold stock on the tables.

DOUBLE-END TENONERS are highly developed machines that accomplish a wide variety of cuts at one passage of the work. Their functions have been broadened and increased by individual motors on each cutting head, which are more flexible than the belt-driven heads of earlier machines. This machine originally was intended to cut tenons simultaneously on both ends of a piece of stock. Cutting heads of various types were added gradually for a diversity of end and intermediate cuts.

In essential principles, the double-end tenoner consists of a sole (or bed) plate carrying two pedestals. One pedestal is stationary, and carries all operating switches. The other may be moved along the sole plate to accommodate the work, limited in standard machines to about 90 in. Between the two pedestals, and below the work, a pair of endless feed chains, with adjustable lugs, carry the work into the saws and other cutting units. The feed chains are kept relatively close to the pedestals but are adjustable along a spline feed shaft between them. They are fixed in the horizontal plane, all vertical adjustments being made with the cutter heads. Two idling pressure chains hold the work firmly, operating directly above the feed chains.

For double cut-off and double rip cuts, as in plywood, only one saw is used in each pedestal. This cut is made from above. On modern double-end tenoners, the main cutter head can be tilted to make angle cuts. One or more additional horizontal (sometimes tilting) cutter heads are located on each pedestal to make end tenons, grooved, shoulder or shaper cuts on either or both sides of the stock, and at one or both ends. Each pedestal also carries a vertical cutter head. An arbor can be placed between pedestals for intermediate saws or cutters. Cope units, dado heads, relishing cutters, etc., if required, may be attached in various ways. Jump dado cams can be used to enter and withdraw dado cutters near the edge of the stock. Dovetailing attachments may be used for either male or female cuts. Methods of adjustment, attachment of various cutter heads, and other operating features vary considerably in the product of the several machine builders. The variety of work is limited only by the available cutter heads and the extent to which production runs justify elaborate setup.

Single-end tenoners, with corresponding attachments, are available for short runs. Stock is fed on a roller feed carriage, with the cutting units at the left of the operator.

SANDERS. Power-feed drum-sanders are of two general types. (1) Work is forwarded by a rubber-cushioned endless-belt bed. (2) Work is moved ahead by pairs of pressure rollers. Widths range from 31 to 103 in. Generally, the roll-feed type sands one side only, giving thinner and more accurate surface removal as in figured faced veneers on plywood. Two-side types are available, if there is plenty of surface to be removed, and accurate centering between surfaces is unimportant. Endless-bed sanders sand one side only.

Endless-bed Sanders. In a typical machine of this type, the sandpaper drums, usually three, are on top. They are approximately 12 in. in diameter, covered with felt cushion and sandpaper, sometimes wound spirally, but more often attached by clamps in slots. The feed belt, with rubber cushions, is below. Surface speed of the first two drums usually is 3700 ft per min (1200 rpm); that of the third drum is 5600 ft per min (1800 rpm). Drums revolve against, rather than with the work. The work is fed at speeds ranging from 12 to 24 ft per min. The coarsest sandpaper is on the first roll, and the finest on the third roll. Each roller and the feed mechanism are driven by an individual motor. Motor sizes, depending on machine width, are: first and second rollers, 5 to 10 hp; third roller, 7 $^1/_2$ to 15 hp; feed mechanism, usually, 3 hp. A brush roller is frequently installed at the delivery end to remove sandpaper dust. Standard drums oscillate slightly endwise (75 to 100 per min) to simulate the side movement of hand sanding.

Single-surfacing Roll-feed Sanders. The drum arrangement is similar to that of endless-bed sanders, except that drums are below the work, and sand through slots in the feed bed. There is an idler-pressure roller above the work. Pairs of smooth feed rollers are located at the entering end, on both sides of the center drum and at the discharge end.

The roll type is not well suited to small dimensioned stock. The sandpaper drums are not so conveniently located for paper changing as in the endless-bed type.

Two-side Roll-feed Sanders. The upper and lower drums are directly over each other in pairs, with the same arrangement of pairs of feed rollers as in the single-surface type.

Belt sanders have a 6- to 8-in. endless sandpaper belt running clockwise on two 18-in. pulleys, 8 to 12 ft apart. In the overhead type the work table, moving on ways toward and away from the operator, is below the lower belt, and the smooth side of the paper is against the pulley. In the underslung type, the table is between the belts, with the sand side of the paper against the pulley. In both types, the work is held on the table by stops at the left and an edge clamp at the right. The operator bears down on the cushion pad, hand operated or mounted on two-way sliding levers. The pad is above and applies controlled pressure through the moving sand belt to sand the stock. Belt sanders are preferred to drum sanders for work that requires a thin cut, as on plywood faces.

Stroke sanders usually are used for polish and finish sanding. They are somewhat similar to belt sanders, except that the pad is mechanically reciprocated under weights. The same type of stroke machine is used for rubbing finish, the sandpaper then being omitted, and a rubbing compound used.

Automatic belt sanders for sanding moldings consist of driven rubber feed rolls which carry the stock under a sandpaper belt, and a flexible shoe shaped to the reverse of the molding contour. Feed is 32 to 50 per min.

Specialized types of sanding machines are belts on vertical pulleys for edge sanding; sand disks on rotating horizontal or vertical tables for drawers and boxes; sand drums of large diameter for curved work; sand arbors for chair legs and irregular pieces, etc. A small portable motor-driven belt sander is available for bench use.

Manufacturers of woodworking machinery include: E. C. Atkins & Co., Indianapolis, Ind.; Babcock Machinery Co., New York, N. Y.; Bell Machine Co., Oshkosh, Wis.; Buss Machine Works, Holland, Mich.; G. M. Diehl Machine Works, Wabash, Ind.; Henry Disston & Sons, Inc., Philadelphia, Pa.; Ekstrom, Carlson & Co., Rockford, Ill.; Greenlee Brothers & Co., Rockford, Ill.; Hermance Machine Co., Williamsport, Pa.; Jenkins Machinery Co., Sheboygan Falls, Wis.; Leitelt Iron Works, Grand Rapids, Mich.; Mattison Machine Works, Rockford, Ill.; Mereen-Johnson Machine Co., Minneapolis, Minn.; J. M. Nash Co., Milwaukee, Wis.; Oliver Machinery Co., Grand Rapids, Mich.; Onsrud Machine Works, Inc., Chicago; C. O. Porter Machinery Co., Grand Rapids, Mich.; B. M. Root Co., York, Pa.; Tannewitz Works, Grand Rapids, Mich.; Vonnegut Moulder Corp., Indianapolis, Ind.; Baxter D. Whitney & Son, Winchendon, Mass.; Wilkin-Challoner Co., Oshkosh, Wis.; S. A. Woods Machine Co., Boston; Yates-American Machine Co., Beloit, Wis.

PLASTICS MOLDING

By J. E. Faloon

The economical production of quality molded plastics products is a reflection of careful choice of both the plastic material and the process to produce this material in the desired shape and size. Normally the prospective user of the plastics part submits the proposed design to the molder for cost estimate. At this time the molder proposes such design changes as may be necessary or desirable to facilitate mold construction or improve part design.

Although noteworthy exceptions exist, thermosetting materials (such as phenol-formaldehyde, urea-formaldehyde, and melamine-formaldehyde) are usually molded by the action of heat and pressure in compression molds or transfer molds. On the other hand, the thermoplastic materials (such as cellulose acetate, polystyrene, and methyl-methacrylate) are generally molded by the injection process wherein the material is heated to desired plasticity and injected into the relatively cool mold to solidify. Most frequently this entire cycle takes less than a minute, although heavy plastics sections or certain other limiting features may require a much longer cycle.

15. COMPRESSION AND TRANSFER MOLDING

COMPRESSION MOLDING is that process wherein the molding material is compressed between mating mold halves known as cavity and plunger (Fig. 1). Flow of the material is accomplished by the interaction of heat and pressure. Mold temperatures range from 290 to 350 F, depending on types of material being molded. Pressures required range between 1 and 10 tons per sq in. of projected area of molded part. Molding materials with coarse fillers require the heavier tonnages. Sources of mold heat are influenced by local costs and available supply; steam, high-pressure hot water, electricity, and gas are commonly used. In selecting type of heat supply, serious consideration should be given to the problem of temperature control as some materials and processes may require sensitive temperature adjustment to achieve efficient operation.

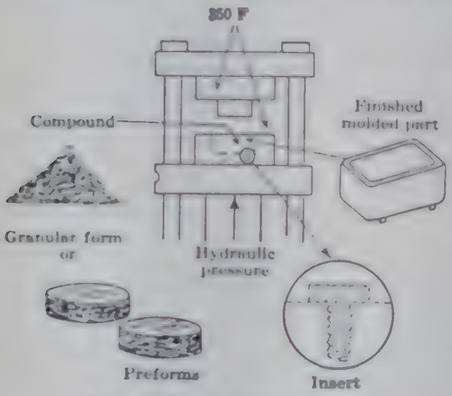

FIG. 1. Compression molding.

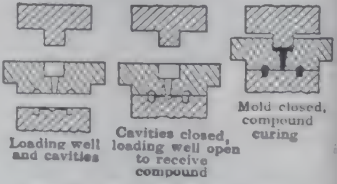
TRANSFER MOLDING is a process for molding thermosetting materials in compression-type press equipment wherein molding compound is loaded into a specially provided loading chamber, then, by the action of heat and plunger pressure, caused to plasticize and flow through channels to the molding cavity where final curing occurs (Fig. 2).

Advantages of transfer molding center about the fact that the molding material is in a semiliquid condition before it is transferred into molding cavities which are already clamped together at their parting line. The semiliquid nature of the molding compound allows it to flow freely around rather delicate mold pins or inserts and thereby has allowed molding of many parts from molds which could not stand up in compression molding. With mold parting line closed before transfer of compound, built-up tolerances can be held closer than in compression molding. This characteristic facilitates flash burr removal and is especially worthwhile on parts molded from compounds that contain coarse fillers.



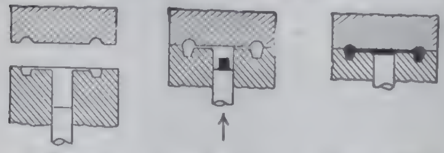
Loading well and cavities

Cavities closed, loading well open to receive compound

Mold closed, compound curing

FIG. 2. Conventional transfer molding.

Along with the numerous advantages of transfer molding, consideration must also be given to certain matters of expense inherent in the process. One of them is the item of compound waste since a slug of material remains in the loading well with each molding cycle. Since this is thermosetting material it cannot be reused. Another problem that must be investigated is location and removal of the molded gates where compound is introduced into the molded part. The optimum condition would be in the use of a small gate located at some inconspicuous spot on the molded product. Since optimum conditions seldom exist, it is frequently necessary to provide for a grinding or sawing operation to remove the gates and, if appearance is paramount, it may be necessary to buff the gate area.



Mold open plunger retracted

Mold closed, compound loaded, plunger advancing

Mold closed, plunger advanced, cavities filled and compound curing

FIG. 3. Plunger-type transfer molding.

Although there are several variations of transfer molding, two basic types predominate. The first of these types is the three-piece mold, as illustrated in Fig. 2, which consists of a loading cavity and plunger connected through sprue and runners to the molding cavity and plunger. All these members are appropriately contained in mold frame components; commonly the loading cavity and molding plunger are fastened in the same center frame member.

The other popular variety of transfer molding consists fundamentally of a two-piece mold clamped together by the normal action of the molding press. This variety, sometimes known as plunger-type transfer molding, is illustrated in Fig. 3. A separately actuated plunger supplies the pressure for transferring material to the cavities. Frequently this type of operation is dependent on electronic preheating of compound to achieve maximum refinement of operation. Outstanding rates of production can be attained with use of plunger-type transfer molding. Special equipment to the extent of a separately actuated plunger mechanism to be run in conjunction with standard presses is the only extra requirement. Once obtained, this plunger mechanism is a useful piece of molding shop equipment which might be considered of a standard nature.

CLASSES OF MOLDS. Compression molds may be designed to operate as hand molds, semi-automatic molds, or completely automatic molds.

Hand molds, representing the simplest form of mold construction, are designed to be removed from the press with each molding cycle for loading material and unloading the molded part. Mold heat is supplied by means of hot plates permanently mounted in the press. Molds are opened and parts removed by hand tools or simple auxiliary fixtures in a work table, which should be located adjacent to the press. The cycle is then repeated by loading molding compound in cavity, reassembling mold, and relocating the mold between heated press platens. The advantages of this design are low cost and easy setup. However the slow resultant production rate and high labor costs of hand molds seldom justify their use except for experimental purposes or very low production requirements.

Semi-automatic molds differ from hand molds to the extent that the mold frames include (1) members to eject the molded part by knockout pins, (2) provision for continuous heating of mold, and (3) provision for fixed mounting of mold in press. With this design the normal action of the press is also utilized to open the mold and eject the molded part from the cavity. The press operator has only to remove the molded part to the tote pan, clean the excess flash from the mold, reload the cavity, and operate the press-control levers. Semi-automatic operation is the most widely used compression molding method since the additional expense for frame construction can easily be justified in increased production rates. Although the setup of the semi-automatic mold is not as simple as the hand mold, standardization of frame and press platens design can reduce the average setup to some fraction of an hour.

Automatic molds are designed to operate in conjunction with special presses to supplant the need for manual loading and unloading of the molds. In design, the automatic mold is very similar to the semi-automatic type, but it is mounted in a press which provides hopper feed of the molding compound, suitable timing devices adjusted to suit the part to be molded, equipment to remove all excess mold flash, and provision for fully automatic ejection of the molded part.

PREPARATION OF MOLDING COMPOUND. Although it is possible to use loose molding powder in loading compression molds, it is most often advantageous to compress the loose powder before using. The nomenclature applied to this operation varies among different molding shops but is perhaps known most commonly as *pilling*, *tableting*, and *preforming*. Although attempts are sometimes made to define these terms as being distinctly different, their usage overlaps in practice, and all may be considered as molding powders compressed but not chemically changed since no heat is used in the operation. The benefits from such treatment are numerous. They include (1) ease of handling by press operator and frequent elimination of need for weighing the compound charge since weight of compressed material can usually be held closely; (2) reduction of bulk factor of compound—ratio of volume of a given amount of material before and after molding—thereby lessening the need for building molds with deep cavities and long plungers to accommodate bulky materials; (3) ease of distribution of molding material to sections of the mold that are difficult to fill out with normal placement of compound; and (4) improved transmission of heat throughout the compound (this is very important where materials are preheated before molding).

PREFORMING EQUIPMENT. Three principal forms of preforming equipment are commonly used. They are (1) single-stroke machine, (2) rotary machine, and (3) hand-loaded press. In the single-stroke machine a die equipped with an upper and lower punch is volume loaded with the free flowing molding powder, compressed, then ejected from the machine to ready it for a repetition of the cycle. Normally the single-stroke machine can produce ten to sixty preforms per minute—more in instances where multiple-cavity dies can be utilized. Single-stroke machines may be likened to a motor-driven punch press in fundamental operation.

Preforms may be produced more rapidly on the rotary machine, wherein a series of identical die holes are located on the periphery of a revolving horizontal table. Each die hole is equipped with both top and bottom punches which revolve with the table but are located in the vertical direction by means of a cam track. Through this relation the individual die hole is first volume loaded from a hopper feed, the molding powder is then compressed as both punches simultaneously pass between pressure rollers, and preform is finally ejected before the continuous cycle is repeated. The rotary machines commonly produce 350 preforms per minute, and models are available to produce as many as 1000 per minute, on smaller preforms. In general the rotary machines are used to produce circular preforms while the single stroke can produce any outline compatible with tool-strength limitations on dies and punches. Both single stroke and rotary are normally limited to molding powders which are granular in nature and pour easily through the hopper feed arrangements.

Preforms can also be produced in standard hydraulic or mechanical presses by pressing molding powder in an unheated special mold. This process is frequently used to handle molding powders containing long-fibered fillers which will not flow through hopper feed mechanisms on standard preforming machines. Preforms can also be produced by this method from nonfibrous compounds, but use for these materials is generally restricted to preforms too large to be formed on automatic machines. The formation of this type of preform is much slower than the automatic machines mentioned, inasmuch as the powder must be hand loaded into the cavity. If close control of weights is required, the charge must be weighed before loading.

PREHEATING OF THERMOSETTING MATERIALS. It is common practice to heat the charge of molding compound before loading it into the mold. Probably the greatest single benefit gained is reduction in cure time. Since any reduction in cure time leads to improved production rate with greater return on tool and equipment investment, that benefit is obvious. Other significant benefits include improved flow of compound within the mold, improved insulating properties imparted to plastic by driving off moisture content, improved density of plastic product, and improved product appearance under certain conditions.

The basic problem of preheating is getting the maximum amount of heat into the molding material without causing material to precure and thereby lose its properties of plastic flow. Too much preheat may be evidenced in either of two ways: (1) a total precuring of the compound with a general stiffening or lack of flow and (2) localized burnt spots wherein certain particles may be overheated although the total charge may still retain its flow characteristics.

Hot Plates. Probably the simplest form of preheating equipment consists of a steam or electric hot plate located close to the molding press. Its use requires reasonable caution to avoid localized burning. Steam or electrically heated ovens represent some improvement although they may be awkward to use under many circumstances. Rotating ovens for granular materials are one special form of oven equipment which minimizes tendency of localized overheating.

Infrared heat lamps are widely used for preheating, inasmuch as they produce effective results with almost a minimum investment in equipment. A number of ingenious arrangements can be utilized in locating the infrared lamps for optimum preheat benefits.

Live Steam. Interesting developments are in progress toward use of live steam on molding compounds for preheating purposes. This method is in use in some plants with satisfactory results.

Dielectric preheating is a recent development that has already proved to be one of the milestones in plastics production equipment. These electronic devices are available in a wide range of portable units designed to handle either small- or large-capacity molding charges.

By means of this type of preheater, the molding compound is subjected to rapid changes in direction of application of electrical energy (in the magnitude of several million cycles per second), with an ensuing creation of frictional molecular heat within the compound. Accordingly, the molding compound is uniformly heated throughout in a matter of seconds. The benefits from electronic preheating are worthy of serious consideration from all molders of thermosetting materials.

FINISHING OPERATIONS. In the plastics industry, the term *finishing operations* is rather loosely applied to all process operations which follow the actual pressing operations. Accordingly, the finishing of compression or transfer molded parts may include any or all such problems as removal of flash burrs which occur at mold parting lines, punching holes or slots, drilling, tapping, cleaning flash from metallic inserts, sanding, grinding, buffing, and polishing. The foregoing list is by no means complete but is indicative of the variety involved.

The important place of finishing operations in the overall economy of plastic molding cannot be overemphasized. As an example, one can readily visualize a reduction of pressing price by building multiple-cavity molds. However, if the product of that mold does not lend itself to mass production finishing operation on each part, the savings in pressing may become insignificant.

Rotating tumbling barrels provide an economical means of removing flash from molded parts. Barrels may be built of wood or metal and frequently have flat sides to provide agitation. Some form of speed control is desirable to take care of different sizes and quantities of parts; speeds of rotations generally vary between 10 and 50 rpm. If molded parts are relatively sturdy, tumbling is usually performed by simply rotating a sizable quantity of parts in the barrel. If parts are more delicate, wooden balls or pegs included in the barrel serve as a sort of cushion during rotation. Holes and slots can sometimes be cleaned by including shot pellets, nails, metal jacks, or like articles with the mass being tumbled. If these assisting media are included, a sorting operation is necessary after tumbling; frequently a simple screening operation gives the desired result.

Hand filing is most often used on parts that cannot be tumbled. Basically this is a rather slow operation which subjects the part to hazards of visible file marks. Cooperative effort between part designer and molder can often accomplish much in simplifying the parting line and masking its appearance. Scraping by knife is usually effective, but the operation is more expensive than filing.

Belt sanders can be used to remove flash burr from items such as open-back radio cases and clock cases. The sander can also be used to correct slight warpages which may exist between mounting pads. Since the sanding does not leave a smooth finish, its use is restricted to areas which are concealed in ultimate assembly.

Spindling. Round molded parts are often adaptable to a spindling operation. By mounting the part on a simple rotating fixture driven by a bench motor or lathe, the flash burr is removed by pressing a file against the cut-off edge.

Punching. Multiple holes, odd-shaped slots, etc., can generally be cleaned by use of punching dies. Basic construction may vary from small simple units that are hand powered to semi-automatic power-driven varieties requiring of the operator only the simplest of loading operations. The degree of refinement used in the punch construction depends, of course, on quantities involved and overall economies of the individual job.

Drilling. In drilling plastics parts, care must be taken to avoid overheating the drill since the plastic material is not a good conductor of heat. A jet of compressed air directed on the work acts as the most satisfactory coolant and avoids the need for any expensive washing operation. In drilling deep holes it is good practice to back the drill out of the hole frequently. Overheated drills can result in premature dulling of the tool and may cause cracking, burning, or extreme roughness on the molded part. The user of drills for plastics should investigate special types that are available. Most of these special types are designed to provide wider polished flutes to give plenty of chip clearance to relieve drill heating. Carboloy-tipped drills are useful to minimize necessary resharpening of drills.

Tapping operations require somewhat the same precautions noted for drilling. Two or three fluted taps are commonly used instead of four, as in metal tapping. Chrome-plated taps usually extend tap life. To obtain full thread size, it may be necessary to provide special taps that are 0.005 oversize to compensate for the slight contraction which may occur immediately after the tapping operation.

Polishing. Although the appearance of the molded product is generally dependent on the degree of polish imparted to the mold, it is sometimes necessary to enhance the finish with a buffing or polishing operation. If it is desired to remove completely a mold parting line or blemish, the area can be corrected by pressing it against a rotating cloth belt to which an abrasive compound has been applied. Care must be taken in these operations to avoid exposing the filler in the plastic compound.

There is a wide variety of commercially available polishing waxes for plastics parts (including white waxes for light-colored work). The technique for using them varies with the particular part being buffed and the nature of the wax. In all instances the polishing operation should immediately precede the actual packing and shipping of the product since further handling may disturb the lustrous finish.

Economical finishing methods are a challenge to the ingenuity of those responsible for planning the operations. By clever fixture design it is often possible to combine such operations as drilling and punching, drilling and tapping, and punching and filing.

16. INJECTION MOLDING

In injection molding, thermoplastic molding compounds are plasticized in an appropriate heating cylinder, then forced by plunger action through one or more orifices into relatively cool mold cavities where the material solidifies to the desired shape (Fig. 4). The injection molding press is usually a self-contained unit consisting of the various hydraulic, electrical, and mechanical units which are adjustable to various molding requirements. The granules of thermoplastic material are loaded into a feed hopper from which a controlled quantity is advanced into the heating cylinder with each complete cycle. The heating cylinder is surrounded by electric heating coils or hot oil. Since plastic materials are inherently low conductors of heat, all designs include some form of spreader located in the center of the plasticizing chamber to force the material close to the cylinder walls and insure uniform heating. Enough material for several molding cycles is present in the heating cylinder at any given time. The newly introduced material is as yet unplasticized, the degree of plasticity becoming more advanced until full plasticity is present adjacent to the injection nozzle.

Temperatures of molding compounds vary from 250 to 500 F, depending on characteristics of material being used and also conditions peculiar to the size and shape of part being produced. Injection pressures vary from 10,000 to 30,000 psi.

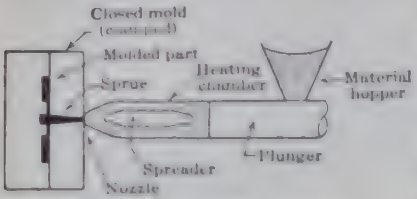


Fig. 4. Injection molding.

To confine the material properly in the mold cavities during the application of these high pressures, it is essential that adequate clamping force be maintained against the mold. Most injection presses provide this force either through a hydraulic ram or through a combination of hydraulic ram and toggle action.

Injection presses are commonly rated on basis of total weight of material which can be molded per shot. This rating necessarily includes not only the net weight of desired molded parts but also that material necessary for sprues and runners. If compounds with low specific gravity are to be used (such as polystyrene or polyethylene), the rating in ounces per shot is reduced in proportion to the lower specific gravity. Machines for injection molding can be set to operate either fully automatically or semi-automatically at speeds up to about five shots per minute. Since production rate is largely dependent on time necessary to force material from the heating cylinder into the mold plus time required to chill this material in the cavities, few parts can be molded at such rapid cycles.

FINISHING OPERATIONS ON INJECTION MOLDED PARTS. One of the basic economies of injection molding can be found in its ability to produce parts without flash along the mold parting line. Accordingly it is frequently necessary only to remove the sprues or gates to provide the finished part. This removal is sometimes accomplished with such standard shop tools as knives, shears, snips, saws, or grinding belt. Frequently, however, it is expedient to provide special milling fixtures, shear fixtures, or other devices to suit the particular job.

Where grinding operations are required it may be necessary to use a water-lubricated belt or wheel to prevent overheating and possible distortion of the molded part. The same principles may apply to drilling, tapping, and other machining operations, to prevent overheating by use of coolant, reduced speeds, and possibly special chip relief on the cutting edges. If coolants other than water are used, their compatibility with the particular type of plastic must be considered.

Thermoplastic parts can be polished on fabric wheels. Very light pressures should be exerted to avoid softening through generation of heat. A number of successful polishing compounds, commercially available, are prepared to supply desired lustrous effects on specific plastics materials.

17. COLD MOLDING

Cold molding is a term applied broadly to a varied family of plastics which are pressure molded (with little or no heat) and cured by a post-molding bake that may require several hours or days. Cold-molding materials fall into two categories—those of refractory and nonrefractory binder content.

The nonrefractory type includes binders of either bituminous or phenolic origin. Refractory types are of a variety of clay, cement, or silicate combinations, and logically their right to be classed strictly as plastics may be challenged. However, their processing technique is so closely allied to the plastics industry that they are generally accepted as such.

The usual molding process consists of loading the necessary volume of molding compound into the molding cavity and applying pressure through the action of a quick-operating press. Intricate molded parts may require special placement of the molding compound to insure proper density since very little actual flow of the compound occurs. Also trial and error may require that the pressure be applied several times in rapid succession on each load to pack the compound properly.

Curing of cold-molded parts requires controlled temperature ventilated ovens which are capable of progressively raising the temperature to desired levels. Required temperatures vary with specific compounds and part design. However, baking is generally started at a low level to drive off volatile content and gradually raised to avoid distortion and blistering. Ultimate baking temperature may be as high as 500 F, and overall time may be as much as a week or more.

Cold-molding presses may be similar to types commonly used for compression molding, namely, the hydraulic cylinder vertical action. However, fast-acting mechanical types which exert their force through a crank arm motion are well adapted to the cold-molding operation.

18. EXTRUSION MOLDING

Extrusion molding is that process wherein articles of uniform cross section are formed by forcing the softened material through a die opening which is substantially the same shape as the cross section of the article. Typical extruded parts are rods, tubes, and decorative strips. Variations of this basic process include processes for continuous coating of insulated wire, clothes line, and similar articles.

Extrusion molding is generally limited to the thermoplastic materials, although some examples of thermosetting products have been in production.

The usual construction of an extrusion machine consists of a hopper-feed heating cylinder through which the material advances by means of a screw feed mechanism. Heat may be supplied by hot oil, steam, or electric units. At the forward end of the heating cylinder the plasticized compound is forced through the die opening to a continuous conveyor or *take-off* belt.

The successful operation of the extrusion machine requires a careful balance between the temperature of the heating cylinder, rate of screw feed, and speed of take-off belt. Because the raw material must be free of excess moisture, it often is necessary to preheat it before putting it into the hopper. Rates of production vary with material being extruded, capacity of machine, and particular shape being formed. Increased product strength can sometimes be achieved by stretching the product slightly as it is extruded (by advancing speed of take-off belt) and thereby orienting the structure.

19. LAMINATED PLASTICS

Sheets of materials united by a resinous plastic comprise the family of laminated plastic materials. Materials united by this process include cloth, paper, wood, asbestos cloth, glass mat, and woven glass. Laminated materials formed under pressures in the magnitude of 1500 psi, or more, are known as high-pressure laminates. Low-pressure laminates, a more recent development, are formed with pressures of 300 psi, or less. Temperatures in the range of 300 F are commonly utilized in laminating.

Resins most frequently used in laminating are of the phenol-formaldehyde type suspended in a suitable solvent and supplied as a varnish. Urea-formaldehyde resins are available for decorative applications. Melamine formaldehyde may be specified for special electrical properties, low water absorption, and decorative properties. Filler material can be impregnated by a continuous process wherein the rolls of paper (for example) are unwound, passed through a varnish bath, then passed through squeeze rolls which remove the excess varnish. The impregnated material continues through a drying oven where solvent is removed. With proper apparatus, much of this solvent can be recovered.

An alternate impregnating process involves use of a pick-up roll which rotates in the pool of varnish and transfers the varnish to the surface of the material sheet. This method is usually reserved for certain rod and tube applications which are built up from relatively thin stock.

LAMINATED SHEETS. In the production of sheets, the impregnated filler is first cut to size, then stacked into the necessary number of laminations to produce the desired finished sheet thickness. Several sheets of laminated stock can be produced simultaneously in one press opening by stacking multiple "build-ups" separated by a metal plate. The surface finish of the laminated sheet is determined largely by the finish on these metal sheets; a high polish, satin finish, or a number of other variations, can be provided.

Multi-platen presses are used for high production of laminated sheets. A typical press of this description would have perhaps fifteen openings which open vertically in an accordion-like fashion to permit horizontal placement of the multiple build-up in each opening. Platens are individually piped for steam with flexible pipe joints to follow the opening and closing of the press. Curing of the sheets requires temperatures of about 300 F (necessarily less for urea-formaldehyde resins). Cure times range from 5 min on very thin sheets to several hours on thick plates. After necessary cure (while material is still under pressure), cold water may be circulated through the platens to eliminate blisters and warpage and provide best surface finish. Edges which overhang the separating plates must be trimmed. Thicknesses ranging from 0.010 to 12 in. are produced from this basic process.

DECORATIVE AND GRAPHIC LAMINATES. By taking advantage of the built-up nature of the laminate, many useful combinations can be produced by incorporating layers of different types of sheets to provide an effect unlike the individual components.

By sandwiching layers of white urea-formaldehyde-treated sheets between thicknesses of black phenol-formaldehyde sheets, engraving stock can be produced. Items such as name plates can then be made by cutting desired letters or numbers through the outer black layer to expose the white core.

Graphic laminates are produced by embedding the printed sheet on or just below the surface. Techniques employed vary under different conditions. In some instances the sheet containing the printed copy or design is impregnated with resin and inserted with a very thin impregnated translucent overlay sheet on top of the stack of built-up layers, then pressed in the usual manner. These other sheets can be of regular economical core stock and of sufficient number to give desired thickness.

A variation of the aforementioned process involves use of a similar translucent overlay sheet with the copy or design printed (in reverse) on the underside. The economies of this method are apparent; however, its use is normally restricted to high-production operations.

In some instances it is undesirable or impossible to submit the printed sheet to an impregnating operation. This can be avoided by printing the design on a very thin sheet and stacking it (without impregnation) between the impregnated overlay sheet and an impregnated background sheet.

A sheet of metal foil can be included within the laminated build-up to make the finished product resistant to cigarette burns. The high rate of thermal conductivity of the metal foil prevents burning by distributing the concentrated heat over a wide area.

MOLDED LAMINATING. Blanks cut from impregnated laminating stock are stacked and subjected to heat and pressure in compression-type molds to provide molded laminated products (Fig. 5). Unlike compression-molded plastics, very little flow occurs during the molding process. Hence product designs should be free of sharp corners and intricate ribs. Uniform cross sections are ordinarily desirable, although nonuniform sections can be molded by stacking extra thicknesses of impregnated stock at desired locations.

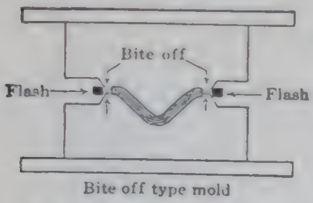

FIG. 5. Molded laminating.

A variation of molded laminated technique that can be used for rayon spinning buckets and similar applications involves use of coil-wound impregnated material. The coil must be wound with a center hole to fit over mold core pin or insert. Likewise the outside diameter must be held to fit into the mold cavity.

LAMINATED RODS AND TUBES. Two basic production methods are available for manufacture of laminated tubing. These products are known as rolled tubing and molded tubing. For rolled tubing the impregnated paper is wound under tension over heated steel mandrels. During this operation pressure and heat are applied through pressure rolls. When desired size is reached, the mandrel and tubular wrapping are removed intact to an oven, where curing is completed. With completion of cure, the mandrel is stripped out and the completed tube remains except for trimming to length.

Molded tubing is first wound on a mandrel similar to the rolled product. However, the mandrel and wrapping are next transferred to a heated compression-type mold composed of semicircular mating mold halves. Usually each mold contains several cavities so that several wrapped mandrels can be molded simultaneously. The molded tubing provides a product of superior strength but requires an additional problem of removing the flash excess which "bites off" at the mold parting line. This is commonly removed by centerless grinding.

Molded rods are formed like molded tubing except that the impregnated material is wound on a small diameter mandrel, which in turn is withdrawn before the compression molding operation. With the action of heat and pressure in molding, the space originally occupied by the mandrel disappears, and a thoroughly bonded rod results. As in the case of molded tubing, the flash line must be removed by grinding.

LOW-PRESSURE LAMINATING is a means of molding resin-coated or resin-impregnated plies of paper, cloth, woven glass, or wood by means of heat and relatively low pressures. Although no fixed line of demarcation exists, pressures used are seldom more than 300 psi with the majority of applications under 100 psi. Although there is considerable variation in techniques, the fundamental process usually involves use of a rigid mold half and also a nonrigid half (such as a flexible rubber diaphragm), through which molding pressure is transferred (Fig. 6). A typical low-pressure laminated construction of a curved panel is as described in the next two paragraphs.

The mold half conforming to the outside contour of the panel is made from some rigid material which can economically be formed to the desired shape. Inasmuch as low pressures are involved, this mold half may be made from such materials as wood, plaster, concrete, metal, or certain plastics. The required number of plies of impregnated laminating stock are clamped or stapled to the mold form in such fashion as to conform as nearly as is practicable to the mold contour. If size permits, both the mold and the built-up plies are placed inside a flexible bag with a vacuum connection which causes the bag to follow the mold contour. Care must be taken at this stage to avoid wrinkles between the rubber bag and the built-up plies since that condition would result in a similar wrinkle on the molded part.

The rubber bag and its contents are then placed in an autoclave, sealed, and subjected to steam pressure (Fig. 6). Under these conditions of heat and pressure, the laminated plies are molded to the desired shape.

FIG. 6. Low-pressure laminating.

The foregoing example utilizes but one of many approaches to low-pressure laminating techniques. Variations in product design may dictate whether the inside or outside contour should be formed in the rigid mold member. Likewise, low-pressure laminating is not restricted to the flexible diaphragm technique. Such articles as cooling-tower fan blades 6 ft in length are successfully produced at low pressures between rigid mold halves which are channeled for steam heating.

While the basic resins used in the low-pressure field are similar to those utilized in high-pressure work, they are necessarily modified to provide for the special molding problems to be encountered. Lower curing temperatures must be provided through inclusion of suitable catalysts since the flexible diaphragms will not withstand high temperatures such as are used in high-pressure laminating. Likewise, since the plies must be formed to approximate final shape during the preliminary build-up operation, it is necessary to have a highly flexible material at this process stage. To achieve this quality, the drying which immediately follows the impregnation is not permitted to advance to the same point used for high-pressure work. With this higher moisture content, a more readily formed material results.

The unique features of low-pressure laminating techniques have broadened the field of plastics applications. Molded parts of almost unlimited area can be produced, such as boats and airplane fuselage and wing sections. The wide variety of structural materials offered provide lightweight products which can give high strength, electrical insulation, corrosion resistance, and excellent appearance if desired. Because the process can be used with low-cost mold equipment it can be a useful development process to prepare the way for more substantial investments in high-pressure mold equipment.

20. MOLD DESIGN

Basically a mold consists of a plunger and a cavity which form the actual molded part. Supplementing these are the frame components which provide support and guidance and also the operating members which simplify removal of parts from mold. A typical mold for a plastic cup (Fig. 7) illustrates the fundamental components normally required in a semi-automatic compression mold.

MATERIALS. The mold plunger and cavity may be made from alloy steels or tool steels. For general-purpose applications a reliable degree of success has been reported in the use of SAE 3310 alloy steel. When properly carburized this chrome nickel steel provides uniformly hard case (Rockwell 56-60C), an exceedingly tough core, and a minimum of hardening distortion.

Cavities formed by the hobbing process (wherein a hardened steel master is sunk under pressure into a soft steel blank) require a milder steel receptive to this means of forming but capable of hardening to withstand molding service conditions. Another chrome nickel steel, of the SAE 3115 type, has met these requirements well. The lower chrome and nickel content represents some sacrifice in core toughness by comparison with 3310, but the ease in hob sinking places it much in demand for this type of construction.

Advocates of tool steel as a mold material claim that such steel, because of its deep hardening properties, gives longer service life and is not as subject to crushing under high molding pressures. In general this class of steels is subject to a greater hardening distortion. A wide variety of suitable tool steels are commercially available. One formulation of chrome silicon tool steel that finds considerable usage is of the following approximate analysis (in percentages): carbon, 0.42; chromium, 1.45; vanadium, 0.25; manganese, 0.30; and silicon, 1.45.

FIG. 7. Conventional bottom-knockout compression mold.

Where possible, mold pins are commonly made from commercial drill rod or music wire. Drill rod (hardened to Rockwell 48-50C) is usually preferred. Music wire (without further hardening) is used for long slender pins which are subjected to some flexing action in service. Since music wire tends to score where friction with a mating mold member is encountered, its use may be somewhat restricted.

Plate steel is usually utilized for many of the miscellaneous frame components. This low-carbon steel, produced by the open-hearth process, is both adequate and economical because cleanliness of steel is not of primary importance here. Retainer shoes, steam plates, parallels, and knock-out bars are examples of this application. Although these members normally do not require hardening, as much as $^1/_{16}$-in. depth of case can be obtained by carburization although considerable correction of distortion may then be required.

INJECTION MOLD. The fundamental construction of an injection mold follows along the same lines noted for the compression mold except that provision must be made for a sprue bushing through the top retainer to convey the plasticized compound from the injection machine nozzle to the mold cavities. A representative injection mold is illustrated in Fig. 8.

CAVITY DESIGN. Several types of cavity design are available to produce any given molded part. In order to compare these types, the molding of the same plastic cup will be compared with the different cavity designs applied.

Flash Type (Fig. 9). Usually one of the simplest plunger and cavity relationships is obtained from the flash-type design. It will be noted that the cavity is machined only as deep as the desired molded part and the excess molding compound overflows only in a horizontal plane. While this construction may be the most economical from standpoint of original tooling, overall advantages and disadvantages should be considered before selection of this (or any other) plunger and cavity design.

Inasmuch as any excess molding material escapes quite readily over edges of cavity, the charge of material does not demand precise weight control to provide moldings with a thin flash edge. Conversely, however, this same characteristic may contribute to excessive waste of expensive molding powders. This lack of positive entrapment of the molding compound also makes it difficult to achieve high density moldings on intricate part designs since the material may escape from the cavity before the intricate section is filled. High bulk factor compounds present another problem since it may not be possible to include the necessary weight of unmolded compound in the open cavity. This condition can be alleviated by preforming the bulky material or double loading. Double loading amounts to loading the open cavity with the maximum amount of compound, quickly compressing the mold, reopening, and loading in the additional compound. While necessity may sometimes demand this method, the momentary action of heat and pressure on the partial load may result in a line of lamination within the product, so that this practice should not be encouraged.

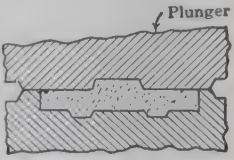

Fig. 9. Flash-type cavity design.

A characteristic of the flash-type design which contributes to low maintenance costs is the absence of any vertical rubbing action between plunger and cavity members. This means, however, that the mating members depend entirely on mold guide pins or built-in interlocking guides. It is essential to maintain the guide pins or interlocking guides diligently if reasonably close dimensional relation between elements molded on plunger and cavity are required.

Within limitations noted, flash-type design is used for compression-type molding. Of perhaps greater significance, however, is the almost exclusive use of flash-type cavity design for transfer and injection molds. In these instances the choice is entirely a matter of tool economy. Since the molding compound is introduced independently into the closed cavity in a semiliquid condition, the problem of loading space is nonexistent, and good molded-part density is achieved by adequate pressure on the material as it is introduced into the cavities.

Positive Type (Fig. 10). The action of the truly positive design may be likened to that of a piston trapping the molding compound and forcing it into the cavity. Inasmuch as there is no land surrounding the cavity, the full molding pressure is exerted against the compound, and the resultant density of the molded part is uniformly good. Uniformity of flash burr is another characteristic of this type of mold since the only flash escape occurs as a vertical burr between the fit of the plunger and cavity walls. Excellent alignment between plunger and cavity may be expected from this design.

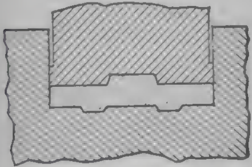

Fig. 10. Positive-type cavity design.

One of the critical features of this type of mold is the necessity of accurate weighing of the molding compound. Any excess material simply tends to increase the thickness of the part, and it is therefore difficult to maintain close tolerances on vertical dimensions.

Another feature which may discourage selection of this design is the item of mold wear due to the rubbing action that usually develops between plunger and walls of the cavity.

Some hand molds of the truly positive variety for molding simple parts such as disks have been constructed without use of guide pins or butt pads. Such molds may be intended for molding disks of various thicknesses, vertical dimensions being controlled solely by weight of compound loaded in mold. The conventional truly positive mold, however, utilizes guide pins to assist in mold assembly and installation and also utilizes external butt pads to prevent plunger from striking bottom of cavity if mold is closed without containing molding compound.

Semipositive Type (Fig. 11). The semipositive design illustrated is a variation of the basic truly positive type. This design behaves somewhat as a flash-type mold until the last fraction of an inch of closure, when the short positive portion of the plunger enters the cavity depression. This design permits overflow of slight excesses of compound charge while retaining good alignment between plunger and cavity. The uniform burr characteristic is especially beneficial for finishing operations, particularly if belt sanding can be utilized.

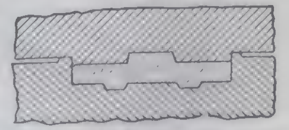

Fig. 11. Semipositive-type cavity design.

Landed Plunger Type (Fig. 12). This design incorporates many of the desirable features of other types previously described. Loading space is attained by allowing necessary space in cavity block above cavity cut-off line. The entering plunger provides excellent alignment between elements molded above and below the parting line. Wear which may occur between plunger and cavity walls ordinarily does not affect the molded part since these lines of friction are outside the outline of the molded part. Reasonable control of compound weights is required although the situation is far less critical than in the truly positive design.

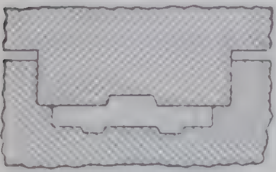

Fig. 12. Landed plunger type cavity design.

In estimating mold construction expense it must be remembered that the cavity of the landed plunger design must be machined at a level which is depressed because of the built-in loading space. The deep machining required may be somewhat more expensive than that of a flash type for instance. Because of the many obvious advantages of the landed plunger type, the added initial expense is usually rewarded with excellent performance. This is verified by the widespread employment of this design for compression molds.

Subcavity Type (Fig. 13). This is a hybrid variety which may be adapted to high-production multiple-cavity molds for relatively small simple parts. A horizontal line of flash will be noted between the various individual cavities, but the extremities of the common cavity area are of a landed plunger type. The operating economy of this type of mold may be realized in considering the ease of loading compound into such a common cavity. Rather than having to load each cavity with an individual preform, the entire lot may be loaded with one large preform. Rather high molding pressure should be planned to assure minimum flash thickness between the individual molded parts. With careful consideration of the foregoing characteristics and qualifications, this design may contribute to very economical production of selected molded parts.

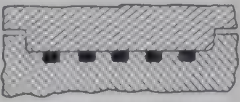

Fig. 13. Subcavity design.

21. MOLDED PART DESIGN

In addition to providing necessary functional requirements, the optimum molded part design should give consideration to factors involving mold making (economy of construction and strength of mold members) and simplification of processing problems. The latter includes simplification of pressing operations, finishing operations, handling and shipping. All the foregoing involve savings reflected either in the form of reduced costs or improved delivery on the molded product. Although it may not be possible to fulfill all these considerations, the economies involved should be carefully explored.

RADII. In general a radius of 1/32 in. or more is preferred to sharp corners throughout the cavity. (The mold cut-off line is the outstanding exception since a radius at that line requires expensive matching of upper and lower mold members. Another exception exists where it is necessary to build up sections of steel to form the cavity.) The corner radii may be formed by normal milling cutters. A sharp corner usually requires laborious hand filing and chipping of the mold steel.

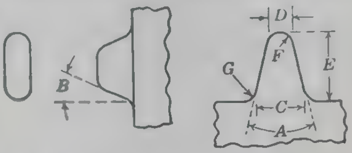
Round corners provide better flow of compound and generally improve the strength and appearance of the part. Square corners may create "dead spots" in the mold since flow direction of compound is changed abruptly and may result in poor knitting of compound in adjoining areas. Certain materials such as urea formaldehydes are especially susceptible to this condition, and in them age cracking may result.

SLOTS. Deep slots must be formed by a correspondingly long blade of steel. If these are made integral with the main mold member they may crack during the hardening process or under service conditions. In this circumstance, some insurance can be allowed by setting in this blade with a sturdy embedded shank. The outline of this shank will show on the face of the molded product. If design permits, added mold pin strength can be gained by rounding out the center portion as shown in Fig. 14.

Fig. 14. Mold pin to form rectangular slot, left, can be strengthened by rounding out center portion as shown at right.

TAPER on vertical molding surfaces aids in ejection of part from the mold member. Specific recommended tapers vary with the particular part design and type of plastics material being utilized. If design permits, it is desirable to allow a 1-degree taper per side, although deep barriers or bosses may require 3 to 5 degrees. Many plastics molders work to as little as a quarter degree per side on most vertical surfaces.

RIBS are commonly used to add mechanical strength or increase electrical creepage distances. They also may improve moldability of a part by improving flow of material to remote areas of the mold. In general, ribbing may improve warpage control although it may be desirable to stagger the rib pattern to interrupt shrinkage tendencies over large areas. Rather than plain surfaces may evidence a shadow effect from ribs on the opposite face (particularly true in translucent materials). The sudden increase in cross section may also contribute to sink spots. Either the shadow effect or the sink spots can usually be rendered unnoticeable if the plain surfaces can be interrupted with a decorative pattern. Well-proportioned rib design is illustrated in Fig. 15.



Recommended proportions for ribs							
	A	B	C	D	E	F	G
Hot molded	10°	5°	n	$n/2$	$3n$	$n/4$	$n/4$

FIG. 15. Rib design.

HOLES. Since molded holes are formed by steel mold pins which must withstand bending or breaking action of the molding compound, the designer must avoid exceeding certain proven limits of slenderness. For compression molding the depth of blind holes is generally limited to twice the diameter; if the diameter is $^{1}/_{16}$ in. or less, the depth should not exceed the diameter. If deeper holes are required, it may be necessary to mold a drill spot to maximum permissible depth and finish drill as an added operation (Fig. 16*b*).

If thickness of molded part does not exceed foregoing ratios, through holes can be molded by butting the pin against opposite mold member (Fig. 16*a*). The horizontal flash can be removed by a subsequent punching operation.

Through holes can also be molded by butt pins which extend from both top and bottom mold member (Fig. 16*d*). Since the individual pin can be twice the diameter, an overall hole length of approximately four times diameter can be achieved by this method. To insure a through hole, one of the pin diameters should be 0.015 in. greater than the other to allow for possible misalignment between upper and lower mold halves.

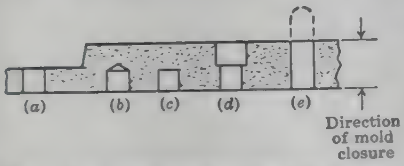


FIG. 16. Alternative pin designs: (*a*) through hole formed by pin abutting on opposite mold half, (*b*) blind hole, with drill point for finish drilling, (*c*) blind hole, (*d*) hole formed by butt pins, one diameter intentionally oversize to allow for mold misalignment, (*e*) through hole formed by entering mold pin.

Transfer and injection molds (wherein the compound is somewhat liquefied before entering actual molding cavity) allow considerable increase of slenderness ratio for mold-pin lengths. It is quite common to allow ratios of three or four to one, and successful moldings of six to one are sometimes practicable.

Through holes can also be made by mold pins which enter a hole on the opposite half of the mold (Fig. 16*e*). This gives the effect of supporting the pin (against sideward stresses) from both halves of the mold. With this added support, slenderness ratios of five to one have been obtained on compression molds and twelve to one on transfer and injection molds. For normal practice it is desirable to stay well under these extreme limits.

Entering pins do not require any flash cleaning around the molded hole as long as a close fit has been maintained between pin and mating member. After some production service a vertical burr is usually present around one end of the hole. It is usually quite light and can be removed by a light burring operation.

The designer must also avoid locating holes too close together or too close to an edge of the molded part. The reasons for this precaution are twofold: (1) weakness of molded part with tendency toward cracking and (2) weakness of the mold member. By remembering that holes are usually formed by pins set into a larger block of steel it can readily be visualized that cracks may occur in the hardened block if there is insufficient space between holes. Holes $^{3}/_{32}$ in. in diameter or less should be at least one diameter from wall of the part. Larger holes may have a lower permissible ratio of wall thickness. In general the distance between holes should be at least $^{3}/_{32}$ in.

Holes should be located parallel to direction of mold travel for simplified construction and minimum operating costs. However, if product design cannot be altered to this extent, the molder has a choice of alternate mold designs to provide holes at right angles to direction of mold travel. The necessary pins can be located on a removable mold member which ejects with the molded part and subsequently is stripped from the product manually or with the aid of fixtures. Before reloading the mold for the next cycle, the loose member is relocated in the cavity opening.

Side holes can also be formed from pins which extend out through the retaining shoe. Obviously such pins must be withdrawn from the molded part before any action of the knockout pins has occurred. Such pins must be adequately reinforced to overcome the internal pressure of the molding compound. This reinforcement may be applied through mechanical locking devices or hydraulic cylinders.

By mechanical cam operation it is frequently possible to translate the action of press opening into a side movement to actuate pins forming side holes. The side molding pins are attached to a sturdy cam block which is moved through an offset in the cam pin mounted on the other mold half. As the press opens, the offset on the cam pin moves the cam block outward so that the molding pin is free of wall of the molded part (Fig. 17). During the succeeding cycle, the same offset in the cam-pin positions the cam block for proper molding through the closing action of the press. In general, this type of cam action is reserved for transfer or injection molding.

INSERTS may be included in molded parts to facilitate subsequent assembly, to provide added strength in specific areas and a conducting path through the insulating material, or perhaps to enhance the insulating properties in localized areas. A variety of insert materials may be used such as brass, steel, silver, Mycalex, glass fiber, and paper, depending on ultimate properties desired.

Brass is the material chosen for the vast majority of insert applications for assembly or conduction properties. Reasons for popularity are threefold: (1) ease of machining, (2) good electrical conduction, and (3) inherent softness which does not damage hardened mold surfaces (particularly in instances where an insert is inadvertently misplaced in cavity and subsequently crushed).

Strips of laminated material, fiber board, or wire mesh may be used to gain mechanical strength in areas of molded parts. In considering such a selection, caution should be observed to avoid serious reduction of some other property of the plastic such as dielectric strength.

A typical example of using inserts to enhance electrical properties is the inclusion of a Mycalex insert in an area subject to electrical arc. The superior arc resistance of this material often suffices for the area in the arc path, whereas the remainder of the part is made from phenolic material that is adequate for the general electrical and mechanical properties.

Anchorage. Allowance must be made to provide adequate anchorage in the molded compound. If round stock is used, a coarse knurl suffices. Hexagonal stock may be grooved to resist pull out; the hexagonal shape resists any twisting action. If stamped, punched, or cast inserts are used, anchorage can be achieved by inclusion of a series of through holes or serrations on the embedded portion.

Locating Inserts. Careful consideration must be given to the method of locating and holding inserts in the mold during molding cycle. Female inserts (Fig. 18) are usually located over mold pins. For best results, inside diameter or minor diameter should be held to ±0.001 in. to permit accurate location, discourage tipping, and minimize compound seepage into the threads. Where inserts must be located on upper half of the mold, a slight taper on the entering portion of the top pins (properly selected with relation to closely held minor diameter) can hold inserts in place if insert is lightly driven over the taper. Knurl on shank of insert should terminate about 1/32 in. from open end to avoid distortion of rim on open face. It is usually good practice to counterbore the mold 0.005 to 0.010 in. deep around the mold pin to allow insert shoulder to project above adjoining surface of molded part. This shoulder effect tends to prevent compound from flashing over the exposed insert face. From an assembly standpoint the raised insert shoulder absorbs the stress from objects tightened against it, thus avoiding any tendency to pull the embedded insert from the compound.

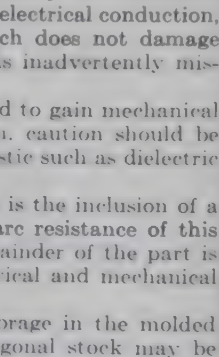

FIG. 18. Threaded female insert.

Rod-type inserts must be located in a hole in the mold, thereby presenting certain molding problems which differ from the female type. If design requirements dictate that the insert be free of flash, very careful consideration must be given to a means of sealing off compound flow lest an expensive and perhaps unsatisfactory finishing operation result. Figure 19 shows three variations in male insert design. The double shoulder provides excellent compound seal and gives added strength against lateral pressures during molding cycle if exposed diameter is small. The single-shoulder type is widely used with reasonably good results. Lacking any shoulder, the third design provides no compound seal and requires an added finishing operation with resultant increase in product cost. This design also may make it difficult to control height of exposed portion of insert. Inclusion of a "seal-ring," as illustrated in Fig. 20, will provide a means of trapping the molding compound below the level of the ring. This ring requires a light pressure to locate properly the insert in the hole in the mold. It is also an effective means of holding inserts in a hole on the top plunger if some design feature prevents locating the insert in a downward position in the cavity.

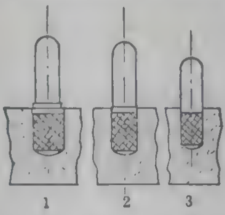

Fig. 19. Rod-type inserts: (1) double shoulder, (2) single shoulder, (3) no shoulder.

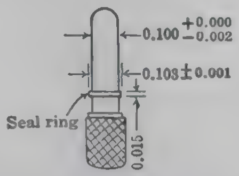

Fig. 20. Seal ring to hold insert in upper half of mold. Also prevents seepage of molding compound beyond level of seal ring.

Stamped, punched, or cast inserts are less frequently used than the machined type but may be selected if they perform some unique function or contribute to overall economy of the design. If chosen, close tolerances are required at dimensions where they must fit the mold. As previously noted, anchorage may be obtained by inclusion of through holes, serrations, or fins in the embedded portion.

22. TOLERANCES FOR MOLDED PARTS

Tolerances are necessary in molded part construction because of unintentional variations in tools, materials, or processing techniques. In the construction of a mold, for example, it is not practicable for the toolmaker to hold every one (of perhaps a hundred dimensions) to precisely the tool drawing dimension. This is particularly true when molds are hardened, polished, and plated after the majority of machining operations have been completed. Molding compounds vary somewhat from batch to batch insofar as shrinkage is concerned. The mold designer must specify all mold dimensions correspondingly larger than the desired molded part, but precision results must be modified by any variation from the nominal shrinkage that may be present in the particular batch of material being used. The final result is also subject to normal variations such as length of cure, amount of preheat, mold temperature, and prevailing temperature and humidity.

TYPES OF TOLERANCES. The average molded part has three different conditions of tolerance because parts are formed between mating mold halves. Dimensions like those indicated by *A* on Fig. 21 may be considered as fixed mold dimensions since they are independent of the interrelation of the two mold halves. Dimensions like those indicated by *B* are known as build-up dimensions and are influenced by the degree of mold closure. Excess molding compound trapped between the mold halves increases the basic dimensions. A third set of conditions (designated by *C*) exists where points being measured are on different halves of the mold. Any misalignment between upper and lower mold halves is reflected in such dimensions.

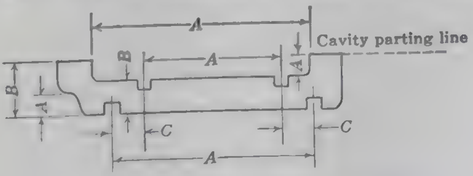

Fig. 21. Conditions affecting tolerance.

The designer should not specify close tolerances unless absolutely essential. Violation of this common-sense principle invariably results in unnecessarily high tool cost, increased product cost, annoying production delays, and higher percentage of rejects.

TOLERANCE VALUES, as suggested below, are intended as a guide for designing molded phenolic parts.

Fixed Mold Dimensions (*A*)

Normal Dimension, in.	Preferable Tolerance, in.	Close Tolerance, in.
1/2	±0.005	±0.002
1	±0.008	±0.003
2	±0.012	±0.005
4	±0.016	±0.010
6	±0.020	±0.015

Build-up Tolerances (*B*)

Small parts, transfer molded	+0.005 in.
Compression molded, wood flour, filled, small parts	+0.010 in.
Compression molded, larger parts, wood flour filled	+0.015 in.
Compression molded, small rag filled	+0.015 in.
Multiple cavity, wood flour filled	+0.015 in.
Large rag filled	+0.025 in.

Note: If depth of molded part exceeds 1 in. it may be necessary to allow fixed mold tolerances in addition to above.

Tolerance for Mold Misalignment (*C*). Additional tolerance of ±0.006 in. (for average molds) should be allowed where points being measured are formed in different halves of the mold. More allowance should be made on very large molded parts.

WARPAGE. A good working tolerance for warpage on most molded plastic parts is ±0.003 in. per in., measured from an average plane through the warped surface.

ADDITIONAL CONSIDERATIONS ON TOLERANCES.

1. Grinding or machining finished part is sometimes the most economical procedure for obtaining extremely close dimensional accuracy.

2. All molded parts are subject to some after-shrinkage upon aging, particularly if subjected to hot, dry service conditions. This shrinkage is extremely slight on mineral-filled phenolics and is most noticeable on ureas and certain thermoplastics. Accordingly dissimilar plastics parts should not be assembled too rigidly together. Assembly of plastics part to metal frame should also be governed by this consideration.

3. Cold-molded parts require a tolerance of about double the preferable tolerances suggested for phenolic moldings.

4. Tolerances on injection-molded parts usually should be somewhat larger than those required on phenolic parts. Because of wide variety of injection materials available, the subject cannot be generalized. Molders or material suppliers should be consulted before such tolerances are established if critical assembly problems are anticipated.

HOISTING

1. MANILA-ROPE HOISTING

MANILA-ROPE HOISTING IN PRACTICE. New manila rope is stiffer than used rope, friction losses due to bending are greater, and hoisting efficiency is less. To determine load capacity of a hoist, note that manila rope limber enough to show higher efficiency than new rope has lost some of its strength and will not be as safe. *Safety in a hoist is more important than efficiency.* For instance, a 1000-lb pull on a lead line might be rated to lift 3400 lb in an eight-part hoist with new rope and 4400 lb with used rope, but the latter would not be so safe.

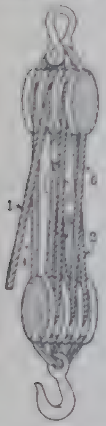

FIG. 1. Triple tackle block.

Manila rope hoists are seldom used with more than six or eight parts of line. Figure 1 shows a six-part hoist with rope properly reeved. The lower block is at right angles to the upper, lead line 1 comes off a middle sheave in one block, and becket line 7 comes off a middle sheave in the other. A six-part hoist has 6 parts of rope at the *movable* block.

MANILA-ROPE BLOCKS are made in a variety of patterns for different services, as occasional or steady, slow or rapid hoisting. Table 1 gives working loads for regular-pattern manila-rope blocks used in pairs. These loads are what the blocks can continue to lift safely in daily service until sheave, pin, and shell are worn out. Bronze self-lubricating bushings prolong the life of sheave and block. If sheaves for hoisting rope can be hung or mounted independently of the block, it is often wise to make them larger than block sheaves. The rope will last longer.

LOADS SUDDENLY APPLIED. Calculations of rope hoists assume the load to be uniformly divided among all parts of rope. With many parts of rope on multiple-sheave blocks, the distribution may be unequal if load is applied suddenly or hoist started at full speed. In such cases, a rope may break at an apparently light load.

Table 1. Working Loads (Pounds) for a Pair of Manila-rope Blocks

(Courtesy of Western Block Co.)

Diam. of Rope, in.	Size of Block	Diam. of Sheave	Singles	Doubles	Triples	Diam. of Rope, in.	Size of Block	Diam. of Sheave	Singles	Doubles	Triples
3/8	3	1 3/4	150	250	350	1	9	5 1/2	2000	2700	3400
1/2	4	2 1/4	300	450	600	1 1/8	10	6 1/4	2400	3100	3800
5/8	5	3	500	750	1000	1 1/4	12	8	2800	3700	4600
3/4	6	3 1/2	800	1200	1600	1 3/8	14	9 1/2	3800	4900	6000
7/8	7	4 1/4	1200	1800	2400	1 5/8	16	11	4400	5700	7000
1	8	4 3/4	1600	2300	3000						

Extra heavy wood blocks and metal frame blocks are good for loads listed for blocks one size larger.

2. WIRE-ROPE HOISTING

EFFICIENCY OF WIRE-ROPE HOISTING. Table 2 shows percentage ratio of theoretical to actual pull (called efficiency). Values in Table 2 probably represent the best that can be obtained in wire-rope hoisting. Loads in the American Bridge Company

Table 2. Percentage Efficiencies of Wire Rope

(American Bridge Co.)

Number of Parts	2	4	6	8	10	15	20
Rope, 5/8 in. diameter	95	90	87	83	80	73	67
Rope, 3/4 in. diameter	93	89	86	82	79	71	65
Rope, 7/8 in. diameter	93	88	85	82	78	70	63
Rope, 1 in. diameter	92	88	84	80	76	68	61

tests were 20 to 60 tons, riggers were skilled, and operating conditions good. Makers' tests of tackle blocks with lighter loads show lower efficiency. Table 3 gives test results that represent average practice in wire-rope hoisting.

Table 3. Percentage Efficiencies with Standard Wire-rope Block

(Courtesy of Western Block Co., Lockport, N. Y.)

Sum of No. of sheaves, both blocks	1	2	3	4	5	6	7	8	9	10	11	12
Efficiency, %	98	96	91	88	84	82	80	76	74	73	70	68

Combinations of rope diameter and sheave diameter are those listed in Table 4.

Table 3 refers to 6 by 19 wire rope used with manufacturers' standard blocks carrying sheaves of sizes shown in Table 4 as related to rope diameters, fitted with self-lubricated bronze bushings.

Table 4. Commercial Sizes of Wire-rope Sheaves

Diameter of rope, in.	3/8	1/2	5/8	3/4	7/8	1
Diameter of sheave, in.	6	8	10, 12	12, 14	14, 16	16, 18, 20

If only life of rope is considered, sheaves of commercial tackle blocks are of too small diameter; practically, it is inconvenient to make them larger. Some single blocks for whip or rapid cargo hoisting have construction refinements, making the blocks safer, more durable, and less troublesome, and add life to the rope. Sheaves are relatively large, of manganese steel, with ball or roller bearings. Shells are cast steel with heat-treated alloy steel pins.

WIRE-ROPE BLOCKS are made as regular, heavy, and extra heavy, with hook (lower block, Fig. 1) or shackle (upper block, Fig. 1) connections. Shackles are used for permanently attached blocks, and hooks for detachable blocks. Hooks fail by straightening, thus giving notice of overloading before failure. Shackles fail by shearing the pin at loads about 5 times those at which round iron hooks straighten, size for size. Hooks flattened to give more depth of cross section at the back are 10 to 15% stronger than hooks bent from round bars. Drop-forged hooks are more generally used and are even stronger. Table 5 gives recommended working loads for a pair of wire-rope blocks. Recommended working loads refer both to ultimate strength of block and its parts, and to durability and safety of block in use.

Table 5. Working Loads (Tons) for a Pair of Wire-rope Blocks

DRUMS AND SHEAVES FOR WIRE ROPE. A wire rope may be used for hoisting haulage or power transmission in various ways.

1. By winding on a drum, grooved or smooth, in one or more layers. The drum may be cylindrical, a frustum of a cone or a combination of the two. Winding on a drum generally is used in hoists and in haulage back and forth.

2. By winding on a winch head. Rope leads on a large diameter, makes several wraps, and pays off on a smaller diameter. Tension is applied to the slack rope. Under load, a side slip tends to wear rope and winch head. This method is used on capstans, car pullers, and for intermittent hoisting and hauling.

3. By winding several wraps of an endless rope on a concave-faced drum or sheave shaped like a winch head. Tight side of rope leads on a high diameter, slack rope leads off a low diameter to a tail sheave to which tension is applied. The side slip of the rope on the drum is objectionable, and this method is not used widely.

4. By winding and rewinding an endless rope around a pair of grooved drums, and from drums to a tail sheave to which tension is applied. This method is used in endless

rope hauling, in traction drives for high-speed elevators, etc. (See Fig. 2.) The smaller this angle, the larger the friction, but the wear on rope and groove from slip, creep, and motion at engagement and disengagement may be destructive if the load is great or the hours of service long.

5. By tractive effort of a sheave with grooves lined with wood, leather, or rubber friction blocks. This method is used for power transmission with high-speed wire ropes. Such large diameter sheaves are used with counterbalanced cages in the Koepe system of hoisting. See Peele, *Mining Engineers' Handbook* (John Wiley and Sons) and catalogs of wire-rope makers.

6. By the use of a grip sheave. Within the rim of the sheave pairs of jaws hinged together are spaced. As they yield to the pressure of the rope they grip it. Springs open the jaws at point of disengagement. This method is used for endless rope carhauls for rope tramways. Older forms of grip sheaves have been known to cut and break ropes; for an improved form (American Steel and Wire Company, Worcester, Mass.) see Ref. 1.

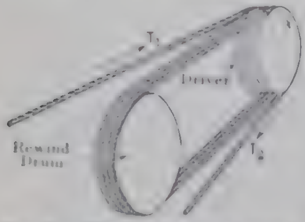

Fig. 2. Winding machine drive.

SHEAVE AND DRUM SIZES. The larger the diameter over which rope runs, the longer it will last, but the cost and trouble of renewing rope usually are less than the difficulty of accommodating larger drums and sheaves and the greater weight and cost of heavier machinery. Tackle blocks, small hoists, shop cranes, derricks, dredges, excavators, etc., are examples of such machinery.

Ropes on small sheaves and drums are subjected both to a larger stress due to direct bending (see Bending Stresses) and to pinching of wires and strands on each other, preventing free movement; also, they may be nicked and broken by the pressure. When a rope runs over a sheave, the tightening of the outer wires tends to twist the rope. The smaller the sheave, the greater the twist, and also the greater the unit pressure of the rope on the sheave tread. This twist under pressure causes the rope to cut the sheave, producing sharp edges which wear away outer wires and shorten rope life. To avoid this trouble, cast-steel sheaves should be used. Manganese-steel sheaves, ground true in the groove, are still better. C. D. Meals (Ref. 2) gives a table of allowable pressures for various kinds of rope on cast-iron, cast-steel, or manganese-steel sheaves. One way to destroy a new rope is to run it on sheaves worn and corrugated by an old one.

Table 6 gives, in the form of ratios of sheave or drum diameter to rope diameter, the following: (1) Minimum economical diameters; these should be chosen where sizes of sheaves and drums are not limited by considerations of available space or weight of parts, and where economy in the use of rope is important. (2) Desirable diameters are recommended for heavy work in important installations, as mine hoists, skip hoists, heavy cranes, hot-metal cranes, and in places where safety is important, and where shutdown from rope breakage cannot be tolerated.

Table 6. Diameter Ratios of Sheaves and Drums for Wire Rope

	6 x 7	6 x 8	6 x 19	6 x 25	6 x 30	6 x 37	8 x 19	18 x 7
Minimum ratios	42	42	30	30	30	18	21	34
Desirable ratios	72	72	45	45	45	27	31	51

PROPER GROOVE CONTOUR. Groove diameter as measured by template or gage should be slightly larger than rope diameter. New ropes are slightly oversize, and for a proper fit groove diameter as measured by template should be larger than nominal rope diameter as follows: $^{5}/_{16}$-in. rope and smaller, $^{1}/_{64}$ to $^{1}/_{32}$ in.; $^{3}/_{8}$- to $^{3}/_{4}$-in. rope, $^{1}/_{32}$ to $^{1}/_{16}$ in.; $^{13}/_{16}$- to 1 $^{1}/_{8}$-in. rope, $^{3}/_{64}$ to $^{3}/_{32}$ in.; 1 $^{3}/_{16}$- to 1 $^{1}/_{2}$-in. rope, $^{1}/_{16}$ to $^{1}/_{8}$ in.; 1 $^{9}/_{16}$- to 2 $^{1}/_{4}$-in. rope, $^{3}/_{32}$ to $^{5}/_{32}$ in.; 2 $^{5}/_{16}$-in. rope and larger, $^{1}/_{8}$ to $^{3}/_{16}$ in. (See Fig. 3.)

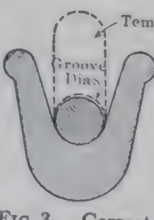

Fig. 3. Correct design of rope groove.

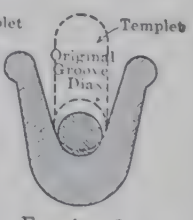

Fig. 4. Correct design with rope worn.

As metal wears away in the tread or bottom of groove, and as rope wears smaller in diameter, there is a new condition of fit, with groove diameter equal to that of the worn rope. (See Fig. 4.) If a new rope runs over worn sheaves, it will not fit the worn groove with proper clearance but will be jammed into it, preventing free movement of the rope, and concentrating abrasion on two lines. Also, there will be a tendency to distort the shape of the rope and cause nicking and breaking of wires. Rope diameter is the largest diameter outside of strands.

DETERIORATION OF WIRE ROPE. Ropes deteriorate by (1) frictional wear; (2) breakage of wires due to defects of materials; (3) breakage due to bending stresses; (4) corrosion, inside and outside; (5) fatigue in steel in the wires. All defects finally show as broken wires, and their appearance guides decisions when to discard a rope. After a new rope has been put in service, the crowns of outside wires wear to an extent necessary to form a wearing surface or contact area to support the rope on sheaves and drums. The reduction in strength of rope is slight and need not cause concern if wear is slow. The appearance of broken wires does not necessarily indicate rapid deterioration. If the rope has started with the proper factor of safety, early abrasion and breakage of wires may be considered normal deterioration within safe limits, but when broken wires continue to appear regularly, removal of the rope should be considered.

Safety of operation depends on strength of the rope as it nears the time of removal. The factor of safety at this time is hard to determine; it depends both on wear and on breakage of visible outside wires, and on corrosion and breakage of invisible inside wires. These combine to cause a reduction in diameter of the rope, which, when greater than wear on outside wires would account for, may indicate internal corrosion. *Coal Age* (Ref. 3) reports a $1\,^3/_8$ in., 6 by 19 mine hoist rope regularly inspected and reported in good condition, which suddenly broke at the part in contact with the head sheave, with cage at bottom of the shaft. Examination of the broken ends showed internal corrosion due to entrance of water; the hemp core was crushed to a pulp 10 ft on each side of break and rope diameter was reduced from $1\,^3/_8$ to $1\,^9/_{32}$ in.

If a rope has not been corroded, its remaining strength may be estimated by counting broken wires in one rope lay in the worst part of the rope, and measuring amount of metal removed by abrasion of outside wires. In one rope lay all outside wires in that length of rope can be seen. Most of the strength of the rope is in these wires, ranging from 83% for 6 by 7 rope to 57% for 6 by 19 Warrington rope. John A. Roebling's Sons Company publishes charts which show, from observed facts of breakage and abrasion, the remaining strength of a used rope, provided there is no internal corrosion. American Cable Company publishes tables showing when ropes in various kinds of services should be discarded. These tables may be summarized as follows. Rope should be discarded when in one rope lay 8 to 20% of visible wires are broken; or when 15 to 25% of wires in one strand are broken, especially if they are adjacent wires; or when outside wires are worn to one-half or two-thirds of original diameter. For high-speed work, heavy loads, and when risk to life or property must be kept low, the lower percentages are recommended. If breakage of a rope merely means a machine stoppage, ropes can be run until outside wires are worn off or until a strand breaks.

Rules and tables for discarding ropes are suggestive only. For instance, it is not possible to group all shop cranes in one class. It is better to treat each installation separately, examine rope systematically and regularly, and note and record breakage and wear of wires. A minimum life based on observed facts can be set up as a standard; if tensile tests of parts of discarded rope show it to have more than requisite strength, considering a proper factor of safety, a new basis can be set up. After a few ropes have been discarded and tested, a standard for that installation can be established that will allow rope to be used with safety and economy.

EARLY FAILURE OF WIRE ROPE. Faults which appear early in the use of a rope should not be laid always to poor manufacture. Careless handling and reeving of the rope often are responsible. The life of a rope often can be increased by putting an obligation of responsibility and competition on the men whose duty it is to use it (Ref. 4).

ATTACHING WIRE ROPE (Ref. 5). The rope may be attached to its load by a socket (Fig. 5) or it may be bent back on itself to form an eye and the loose end clamped to the rope with rope clips (Fig. 6). Properly done, the first method develops the full strength of the rope but has the following disadvantages: poor workmanship is concealed; it cannot be readily inspected; the rope is rigidly held and the effect of bending is concentrated just above the socket; it is more difficult to make. Fastening by clips develops not over 85% of the strength of the rope. This fastening bruises and crushes the rope where the clips are applied, and is likely to slip, but it can be inspected readily and requires little skill in making. Rope makers recommend the socket method of fastening, which, if made according to instructions, never fails. After either a socket or a clip attachment is made it should be tested by making several trips under a heavy load before men are allowed to ride.

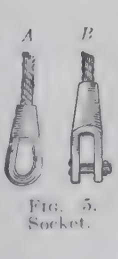

Fig. 5. Socket.

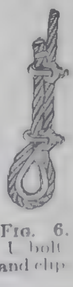

Fig. 6. U bolt and clip

The clip attachment is made as follows. The rope is bent back over a thimble of the proper size and the loose end clamped against the long end of the rope with the proper number of clips. The Crosby type of U-bolt-and-drop-forging clip has proved most satisfactory. The clips should be spaced a distance apart of six times the rope diameter, the drop forging being against the long end and the U bolt against the loose end of the rope. The number of clips required to develop approximately 80% efficiency of the rope and the proper length of wrench to tighten the bolts are given in Table 7. Never put the drop forging of the clip against the loose end of the rope.

Table 7. Number of Crosby-type Rope Clips Required to Develop 80% of Strength of 6 x 19 Plow-steel Rope

Diameter of rope, in.	3/4	7/8	1	1 1/8	1 1/4
Number of clips	5	5	5	5	6
Length of wrench, in.	18	18	24	24	24
Efficiency, %	77	79	77	80	82

The clips must be carefully inspected occasionally and tightened if they show any signs of loosening through the reduction in diameter which comes from stretching of the rope and compression of the hemp core.

Thimbles (Fig. 7) may be held in the bend of the rope by clips or they may be spliced in. A spliced end, properly made, will not pull out, but it will not develop the full strength for ½-in. rope, and not over 60% for 2½-in. rope. Thimbles and sockets form the means of attachment of hooks and shackles and eyes of various kinds. (See Figs. 10, 11, and 12.) For high-tensile ropes (plow steel, etc.), it is best to use the special heavy thimbles and sockets listed by wire rope makers.

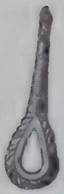

Fig. 7. Thimble.

Swaged or compressed fittings for wire rope are being extensively used on wire rope. Examples of such fittings are illustrated and discussed on p. 6-20.

FASTENING WIRE ROPES TO DRUMS. Figure 8 (Link-Belt Company) shows a method of readily attaching or detaching the rope from the circumference of a drum on an electric hoist. The last groove sweeps with a large radius into a depression which allows the socket on the end of the rope to be slipped into the inside of the drum; a pipe plug closes the cavity and locks the socket in place. By unscrewing the plug, the socket can be pulled out and the rope removed.

Where the end of the drum or its hub is readily accessible the rope can be secured by a few wraps around the hub with the end clipped to itself or to one of the arms or spokes of the drum.

The hole in the rim through which the rope passes should be well rounded to avoid a sharp kink in the rope. Wherever possible the drum should be cast with a ledge or lug to lead the rope tangent to the hub over a radius of 6 or 8 diameters of the rope (similar to Fig. 8). To fasten the end link of a chain to a drum, it is customary to use a forged clamp, tap-bolted to the rim of the drum, and provided with a finger equal in diameter to the size of the chain (Fig. 9).

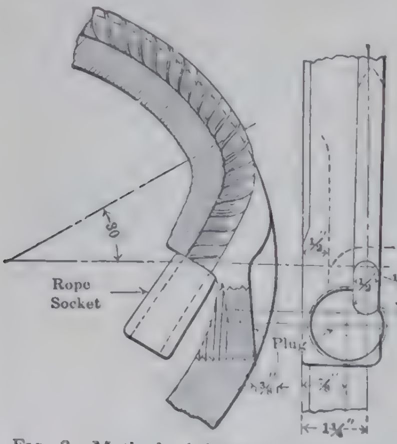

Fig. 8. Method of fastening wire rope to drum.

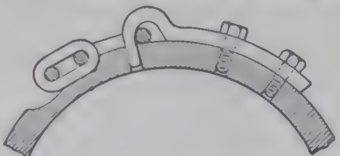

Fig. 9. Method of fastening chain to drum.

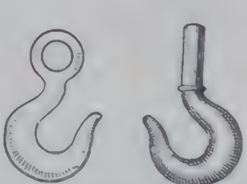

Figs. 10 and 11. Drop-forged hoist hooks.

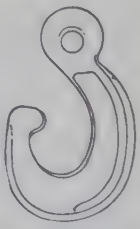

Fig. 12. Bemis safety hook.

DROP-FORGED HOIST HOOKS of steel without welds are made in sizes up to 25 tons capacity. They are heat treated after forging and tested to 50% beyond rated working load. (See Figs. 10 and 11 and Table 8.) Drop-forge companies have stock

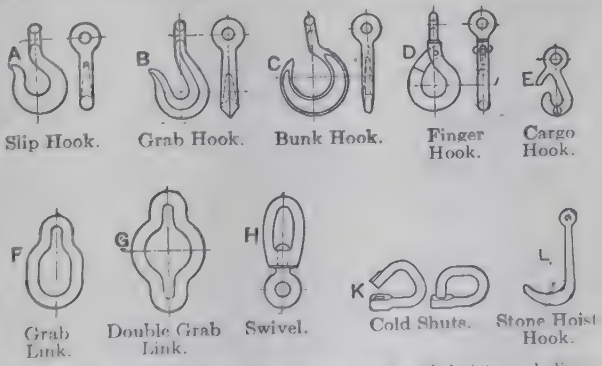
dies for most sizes and furnish hooks in moderate quantities without making charge for dies. Drop-forged hooks of dimensions in Table 8 are good for loads of 3 1/2 to 5 times rating, if sling or fixture rests in the bottom of the jaw. If the load improperly comes on the point of the hook, the carrying capacity is much less. In no event is the hook likely to break suddenly; the jaw will open out first, and signify overloading or improper engagement of the hook.

The Bemis patent safety hook (Fig. 12) (American Locomotive Company, New York) has rated capacities up to 14,000 lb. It is made in four sizes. Hooks fitted with movable guards are not favored by stevedores. They are likely to get out of order, and time is lost in putting slings on or off.

Figure 13 shows various forms of forged connections used with hoists and slings. *A* is a slip hook used on end of rope or chain sling passed around a load to tighten on the load when hoisted. *B* is a grab hook used on chain slings which are not to tighten on the load; the throat of the hook allows the chain to enter but not to slip. *C* is a bunk hook used on tackle to take several rope slings at one time. *D* is a finger hook to avoid the danger of the hook's catching under the edges of hatches in ships. *E* is a cargo hook for the same purpose. *F* is a grab link used instead of a grab hook; one end of the chain sling is fastened to the large end of ring; the chain is passed through and when the loop is of proper size the small end of the link is pulled between two links of chain. *G* is a double grab link used to shorten a chain or join two quickly and temporarily. *H* is a swivel used to prevent twisting of load by twisting of the hoisting rope or chain. *K* is a cold shut for repairing a chain or connecting two chains. *L* is a stone hoist hook, used in quarry work; the points of the hooks engage the sides of the stone blocks.



Slip Hook. Grab Hook. Bunk Hook. Finger Hook. Cargo Hook.

Grab Link. Double Grab Link. Swivel. Cold Shuts. Stone Hoist Hook.

FIG. 13. Forms of forged connections used with hoists and slings.

Steel for hooks, rings, and hoisting fixtures should be of known analysis. Test specimens should be subjected to bending to insure absence of pipes, seams, or other imperfections in the bar. Hot-rolled steel of forging quality, SAE 1010, is used by some makers.

In one important plant all chains, slings, hooks, and lifting fixtures are inspected once a month; parts that can be benefited by annealing are so treated once a year (Ref. 6).

WIRE-ROPE SLINGS, as compared with chain slings, are lighter and, in general, will not fail without warning. Breakage of outer wires is the visible warning, but the inner wires alone will carry loads at which the slings are rated by the makers.

Plain slings are made of standard 6 by 19 or 6 by 37 rope spliced endless, or fitted with sockets, thimbles, or eye ends. In the Atlas patent slings each member consists of one right and one left lay rope braided around a hemp core back and forth so that the sling member has a strength of eight or more strands of the rope. (See Fig. 14.) The ends are loops that can be used as eyes, or fitted to sockets or thimbles. In the Drew sling an endless wire rope is braided into a band about 2 rope diameters thick, 6 or more diameters wide. John A. Roebling's Sons Company, Trenton, N. J., makes slings whose members are of *grommet* construction, i.e., one strand braided back on itself to form a six- or seven-strand rope, endless except for a splice in the one strand. The ends preferably are held by patented thimbles, which are large, permit some slip to equalize the load, and in the form shown in Fig. 15, one thimble can be passed through the other to form a loop or anchor sling. The grommet link (Fig. 16) avoids using a forged steel ring to connect the two or three legs of a sling. All tension comes on a wire-rope ring spliced endless as described above.

FIG. 14. Atlas patent sling.

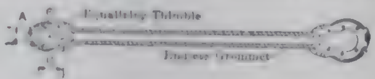


FIG. 15. Grommet sling.

Table 9. Improved Plow Steel Wire Rope Slings

(Courtesy of John A. Roebling's Sons Co., Trenton, N. J.)

The safe load for any number of parts may be obtained from values given below by direct multiplication. Slings 3/8 to 1 1/8 in. in diameter inclusive, 6 x 19 rope; slings 1 1/4 in. in diameter and larger, 6 x 37 rope. All ropes have independent wire rope core.

Diam. of Rope, in.	Safe Load Values When Used in Single Part							
								
	Connection		Connection		Connection		Connection	
	Socket	Splice	Socket	Splice	Socket	Splice	Socket	Splice
3/8	1,000	800	900	700	700	600	500	400
1/2	2,000	1,800	1,700	1,600	1,400	1,300	1,000	900
5/8	4,000	3,600	3,400	3,100	2,800	2,500	2,000	1,800
3/4	6,000	5,200	5,100	4,500	4,200	3,700	3,000	2,600
7/8	8,000	7,000	6,800	6,100	5,600	5,000	4,000	3,500
1	10,000	9,000	8,700	7,800	7,000	6,400	5,000	4,500
1 1/8	12,500	11,400	11,000	10,000	9,000	8,000	6,200	5,700

1 3/8	17,000	16,000	14,500	14,000	12,000	11,300	8,500	8,000
1 1/2	20,000	19,000	17,000	16,500	14,000	13,400	10,000	9,500
1 5/8	23,000	22,000	20,000	19,000	16,000	15,500	11,500	11,000
1 3/4	27,000	25,000	23,000	22,000	19,000	18,000	13,500	12,500
1 7/8	30,000	29,000	26,000	25,000	21,000	20,000	15,000	14,500
2	34,000	33,000	30,000	29,000	24,000	23,000	17,000	16,500

Figure 17 shows a sling with clamp hooks for lifting plate. It has an equalizing thimble, and carries plate clamps with a positive grip. Structural-steel slings may be fitted with a toggle and releasing pin for detaching the sling, when slack, by pulling a hand line from a distance.

The rated carrying capacity of a sling depends on the kind of fittings, the way the sling engages the load, and other factors obtained by experience. Table 9 gives carrying capacities of improved plow-steel slings which bind against the load. If the sling is not in contact with the load or if it passes around a large diameter, so that stresses are not concentrated at corners, safe loads may be increased somewhat above the tabular figures.

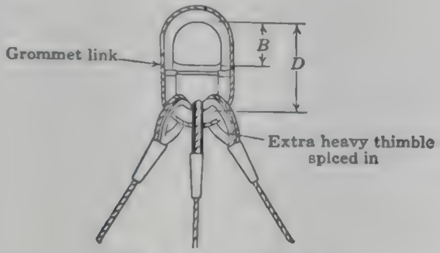

Fig. 16. Grommet link.

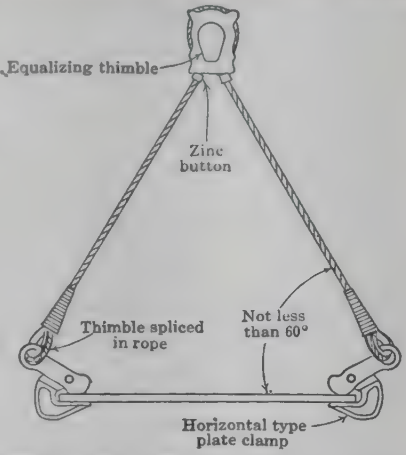

Fig. 17. Sling with clamp hooks for lifting plate.

HANDLING MATERIAL IN BULK

3. WIRE-ROPE HAULAGE

WIRE-ROPE TRAMWAYS, or simply **ropeways,** are transporting systems in which moving carriers or containers hang from a wire rope carried on a series of spaced supports, and are moved along by a rope, generally from one terminal to another. Ropeways that both hoist the load and carry it are cableways.

For distances over a few hundred feet a ropeway often is the best, cheapest, and sometimes only means of transport. Under favorable conditions it is low in first cost, cheap to operate, and maintenance and depreciation are low. Ropeways are durable and serviceable. According to one European builder over 90% of those built by him in 30 years are in use; of those built within 50 years, 75%. A ropeway 18 miles long carrying 36,000 tons a year at one-third the cost of transportation by truck is described in Ref. 1. Tramways are single rope and double rope.

Single-rope tramways comprise one endless moving rope which both supports and moves the carriers (Fig. 1). At the driving terminal is a large grip sheave (see p. 26-04) or a multiple-groove sheave working with a rewind sheave (see p. 26-04). At the other end of the line, an idler sheave with a pull-back weight puts tension in the rope. Towers on the run carry sheaves to support rope and carriers. The carrier has a pair of clamps to grip the rope. In one construction (Pohlig) the grip permits some axial rotation of the rope, to lessen wear on grip and rope. Grips are automatically engaged or disengaged at terminals, and the carrier runs on its own rollers over fixed track to be loaded or unloaded. Ropeways are best built in a straight line, but angle stations can be provided. Single-rope tramways are used for relatively light loads, which can be spaced with some regularity, and where grades on the line are not over 30%.

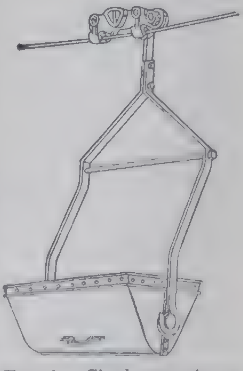

Fig. 1. Single-rope tramway carrier

Double-rope tramways are those most used in the United States; they are suited to a wider variety of loads, grades, and spans than single-rope tramways. They have two track cables, one for loads, one for empties, usually of locked coil construction anchored at one end, with tension weights at the other. The carriers (Fig. 2) have rollers running on the track cables and are pulled along by a hauling rope which they grip. The hauling rope is driven, tensioned, and supported as is the rope of a single-rope tramway. The grip is worked by two jaws on a threaded pin to which a lever is attached. At the terminal a stop throws the lever over and tightens or loosens the clamp.

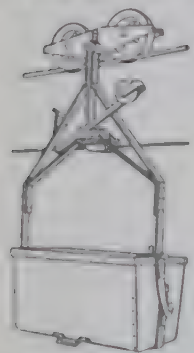

FIG. 2. Double-rope tramway carrier

For details of American ropeways, see Ref. 2 and makers' catalogs. For European practice, see Ref. 3. Costs of handling are compared with costs by other methods in Ref. 4. See also Ref. 5 on recent improvements in automatic dumps, etc.

SUSPENSION CABLEWAYS OR CABLE HOIST CONVEYORS are systems of hoisting and transporting materials consisting of one or two track cables stretched in one span between terminals, a bucket, container, or grab suspended from a carriage running on the track cable, ropes for hoisting the suspended load and moving the carriage, and winding drums for the ropes. In quarrying, rock cutting, stripping, piling, dam building, and many other operations where it is necessary to hoist and convey large individual loads economically it frequently happens that the application of a system of derricks is impracticable, by reason of the limited area of their efficiency and the room which they occupy. To meet such conditions cable hoist conveyors are used, as they can be operated in clear spans up to 1500 ft, and in lifting individual loads up to 15 tons. Two types are made—one in which the hoisting and conveying are done by separate running ropes, and the other applicable only to inclines in which the carriage descends by gravity, and but one running rope is required. In the former the carriage is moved by means of an endless rope. These conveyors are commonly known as *endless-rope* hoist conveyors to distinguish them from the other type, known as *inclined* hoist conveyors.

The general arrangement of the endless-rope hoist conveyors consists of a main cable passing over towers, A frames, or masts, as may be most convenient, and anchored to the ground at each end. Cable tension is maintained by a turnbuckle at one anchorage.

The carriage travels on this cable. It is moved back and forth by means of the endless rope. The hoisting is done by a separate rope, both ropes being operated by an engine specially designed for the purpose, which may be located at either end of the line, and is constructed in such a way that the hoisting rope is coiled up or payed out automatically as the carriage is moved in and out. Loads may be picked up or discharged at any point along the line. Where sufficient inclination can be obtained in the main cable for the carriage to descend by gravity, and the loading and unloading are done at fixed points, the endless rope can be eliminated. The carriage, which is similar in construction to the carriage used in the endless-rope cableways, is arrested in its descent by a stop block, which may be clamped to the main cable at any desired point, the speed of the descending carriage being controlled by a brake on the engine drum.

SLACKLINE CABLEWAY Following is the procedure in the digging, conveying, and elevating of material by a dragline bucket (see p. 26-13) used with a slackline cableway. The bucket (Fig. 6) travels on an inclined track cable, one end of which is anchored. The other end is so rigged to the top of the mast that it can be tightened or slackened by the operator to vary its sag. One end of the hauling rope (load cable) leads to the bucket; the other end winds on a drum. The track cable spans the area served. When it is slack the bucket rests on the material to be dug, the hauling rope is wound in, the bucket digs its load and fills. The track cable is tightened, the bucket raised, and, according as the dump is at the high or low end, the carriage is pulled to or allowed to run to the dump. One man controls all operations. This type of plant is cheaply built and economically operated. It digs sand and gravel from pits and river beds, strips overburden, and makes cuts and fills. By changing the position of the track cable anchorage and turning the mast it will dig a semicircular pit.

CABLE CRANES are similar to suspension cableways, but by having one or both end towers movable they serve a greatly increased area. They are used in building canals, dams, locks, and to serve large storage areas. In American practice, work of this kind usually is done by power shovels (locomotive or crawler cranes) or slackline cableways, or combinations of them, with drag scrapers.

POWER DRAG SCRAPER SYSTEM OF STORAGE. A typical application of this system is a plant receiving coal by rail. The coal-handling system crushes, elevates, and delivers coal to the boiler house, or forms a small pile near the railroad track. Two ropes run across the storage from a double-drum winding machine through tail blocks fastened to back posts. They are hitched to the front and back of an open-end steel box, the scraper. Faced one way the scraper drags coal from the starting pile into storage; faced the other way it drags coal back to the track hopper. If the coal is frozen it goes to the crusher; otherwise the crusher is by-passed.

In small plants, tail blocks are hooked to tail posts, which are short steel columns in concrete piers. They may be hitched to a bridle cable stretched between adjacent posts. In large plants, back posts may be mounted on a car on a standard-gage track, and counterweighted to resist pull of the scraper rope. For high piles the tail block may be carried by a steel tower, 20 or 30 ft high, on a broad flat car on wide-gage tracks. In one plant (Beaumont) the tail sheave is mounted on a caterpillar tractor which can travel anywhere on the storage lot and form a pile of any size or shape.

Advantages claimed for this system are these. (1) Storage area can be any shape or size up to 900 ft scraper travel. (2) Simple machinery, low first cost, cheap repairs, one-man operation. (3) Low fire risk in stored coal; ability to reach fire easily should it occur. (4) Wide range of economical handling capacities up to 1000 tons per hr.

Dragline scraper systems are built in smallest size, $^1/_3$ cu yd; largest size, 12 cu yd. Small drag scrapers are made for mines, tunnels, quarries.

A combination slackline cableway and dragline scraper system was successfully used in digging a canal in Russia and disposing of excavated material. All three towers are mounted on wheeled trucks running parallel to the canal. This combination has a higher capacity than could be obtained with a cable crane (see p. 26-10) spanning the whole width of the plant.

Drag Scrapers in Cargo Boats. A number of self-unloading boats on the Great Lakes and in coastwise service carrying bulk cargoes have a belt conveyor on a boom which can be slung to either side in order to discharge cargo ashore. The conveyor on the boom is fed from an inclined conveyor from the hold of the boat. There are several ways to take material from the hold and deliver it to the inclined conveyor. Some boats have two belt conveyors, others two apron conveyors, in tunnels extending the length of the cargo hold. Another method, patented by L. D. Smith, Sturgeon Bay, Wis., uses a pair of drag scrapers, each operated by its own double-drum winding machine, in two tunnels with smooth steel floors. Material flows into the tunnels through side openings. Along the top of each tunnel is an I-beam trolley track. The haulage cable is hitched to the open end of the scraper; the pull-back cable for each of the scrapers runs through a small tunnel, around end sheaves, over a trolley sheave hung from the I beam, thence to the back of the scraper. The scrapers drop material into a hopper over the inclined conveyor. On the back pull the scraper is lifted up to the trolley, passes over material which has flowed into the tunnel, back to the starting point. Unloading capacities are 750 to 2000 tons per hr. Small scrapers are 4 cu yd capacity; large ones, 12 cu yd. This system has been applied to tow barges with electric motors for operating the winding drums, but without generating plant. Power cables are run from the dock for unloading.

4. LOCOMOTIVE CRANES

LOCOMOTIVE CRANES usually consist of a lower frame fitted with 4 or 8 wheels for use on track, and a rotating upper frame carrying the power plant and operating machinery. A boom, hinged to the upper frame, can be raised or lowered to handle loads at various radii. The crane will act as a portable hoisting engine, a swinging derrick, a grab bucket unloader, or a switching engine. It will handle a lifting magnet, scoop shovel, dragline scraper, or pile driver. Locomotive cranes with (usually) 8 wheels find widest application around industrial plants served by tracks. Besides lifting loads by hook block, they handle pig iron and scrap with a magnet, and shift cars.

Steam-operated cranes require a boiler, fuel tank, and water tank. Usually a licensed engineer is required to run the boiler. Many later cranes have gasoline or diesel engines, which require less space, can be started or shut down instantly, and have lower stand-by expense.

Crawler cranes, instead of having wheels, have a pair of treads made of steel plates linked together and driven by sprocket wheels. The weight is carried by a row of rollers on the lower frame. The width of tread plates and length of assembly make the unit bearing pressure so low that the crane can travel on soft, rough, or uneven ground, and it requires no track or mats. Crawler cranes as made by several companies are fitted with digging shovels, dragline buckets, trench hoes, skimmer buckets, etc., and can be converted easily from one to the other.

The power shovel is for general excavating, digging from the bank, handling blasted rock, and for grading, including shallow cuts below grade. Its particular field is making cuts into and through banks, loading blasted rock on cars or trucks, where the machine stands in the hole or at base of the excavation. It can be used on loose piled materials, but if reach is long or lift high a grab bucket often works better.

The dragline crawler is for removing overburden, digging under water, cutting wide or deep trenches, and where it is necessary to work above material handled. Dragline excavators work outside the hole, and when fitted with long booms can cover a large area, pile material high, and load cars some distance away. The dragline bucket is not so well suited to side cutting as the trench hoe.

The trench hoe is used to dig trenches up to 12 ft wide and 20 ft deep in types of earth that can be cut and that will not cave in. It is faster than the dragline, can be more accurately controlled, and will cut a greater length of trench in a given time.

The skimmer bucket is a form of shovel comprising an open-end box with teeth. It travels back and forth on the underside of the crane boom and is used for grading, leveling, tearing up old pavements, etc.

STORAGE SYSTEMS USING LOCOMOTIVE CRANES. Figure 3 shows a system of storing coal in semicircular piles. Drop-bottom cars discharge to a central pit around which as a center are broad gage tracks for a long-boom crane. In large plants, working radius is 100 ft. The grab bucket has a capacity of 1 to 4 tons of coal which it digs from the pit and drops on the pile; in reclaiming, it digs from the pile and drops into cars. With coal piled 25 ft deep, a crane of 100-ft radius will store 70,000 tons in a full circle with crane tracks covered. By continuing the tracks into more loops, successive storage piles can be formed by one crane. The handling capacity, depending on size of bucket, is 100 to 250 tons per hr.

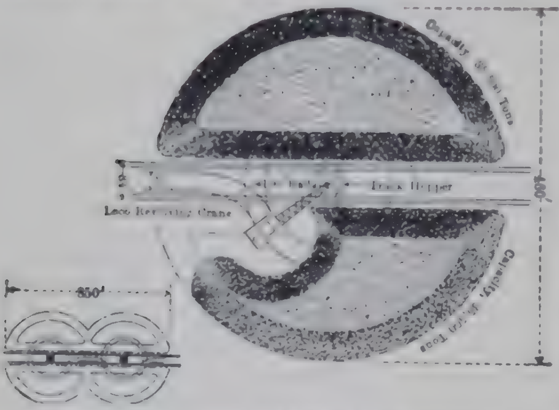

Fig. 3. Semicircular pile system of coal storage.

Locomotive shovel cranes and crawler shovels are used with belt conveyors to remove excavated material or to build levees. Dragline cranes, feeding a system of belt conveyors in tandem, are used in building levees along the Mississippi River. In 1929, over 6,000,000 cu yd were dug from a hill in the middle of Seattle, Wash., by crawler shovels, dumped into feed hoppers, thence to belt conveyors, some of them portable, and carried 3000 ft for disposal. For the system used in building the Grand Coulee dam, see Ref. 6.

5. GRAB BUCKETS

GRAB BUCKETS. Most rope-operated grab buckets, clam-shell buckets, or orange-peel buckets work on the same principle, viz., an upper head, and movable, relative to it, a lower head. The holding line, attached to the upper head, sustains the weight of the bucket when it opens. The lower head is connected to the bowl of the bucket and the closing line, so that when this line slacks the bucket opens. When it is pulled the bucket closes. Various styles of buckets differ in the manner of reeving closing line through sheaves or around a drum (power wheel) or of attaching it to arms or a crosshead so that pulling the closing line will cause the digging edges of the bowl to dig material and fill the bucket. (See Fig. 4.) Very heavy buckets may be operated with two holding and two closing lines to reduce size of rope, sheaves, and drum. Figure 5 is a diagram of two holding lines run from drum H and clipped to an equalizer lever at the top of the bucket. The closing line runs from drum C, around sheaves U and L in the bucket, thence to an anchorage or back to the drum. This is the *fleeting through* method of reeving. If the crane handles a hook block or buckets of different sizes, the bucket is

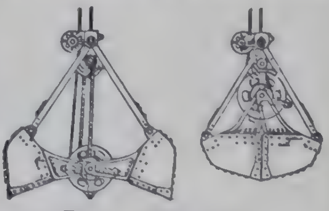

Fig. 4. Grab bucket.

readily detachable if the two closing lines in the bucket are dead-ended, instead of being in one length.

The following is the cycle of operation of any rope-operated bucket. Assume bucket to be in upper position (Fig. 5), empty and closed; the weight is on the closing line. Drum *C* turns to lower bucket; drum *H* pays out holding line at the same rate of travel. As the bucket approaches material to be dug, *H* is braked, *C* pays out closing line, the weight of the parts *L* pushes hinge of the bucket down, the halves open, and the bucket is ready to bite. Both lines then are let go, and the bucket drops on the material. With holding line slack, the weight of the bucket resting on its digging lips, the closing line is pulled in; upper head *B* sinks, bucket closes, digs, and fills. To raise bucket, *C* turns to pull in closing line, which now takes the weight; *H* pulls in the holding line. If the loaded bucket hangs from a trolley or carriage both drums are braked while the carriage moves. To lower the loaded bucket, both drums, under brake control, pay out line. To open the bucket, *H* is braked or stopped, *C* pays out closing line, lower head *A* sinks, and bucket opens. In its traverse back to the loading point, both drums are braked and the bucket stays open.

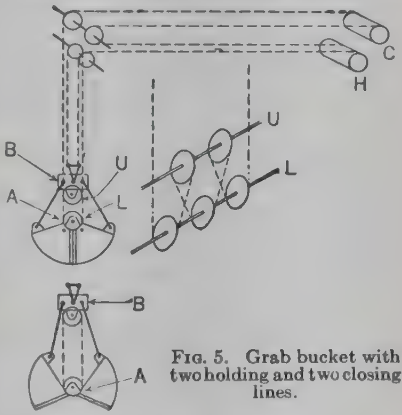

Fig. 5. Grab bucket with two holding and two closing lines.

The choice of a grab bucket depends chiefly on the material to be dug. Buckets with half-round bowls (Fig. 4) will dig loose free-flowing material and coal that is not too lumpy. To dig material that is lumpy or packed hard, the open bucket should have its digging edges in position to penetrate the material and not skid over it.

Orange-peel buckets have a hemispherical bowl divided into sections fitted with digging points. Holding, opening, and closing are the same as in clam-shell buckets operated by two lines. They are made in sizes up to 1 $^1/_2$ cu yd; also in very small sizes that can be used in digging test holes and holes for concrete piles.

Single-line buckets are made in the smaller sizes to rehandle loose material from cars or stock piles or for light excavating. They are hung on a single rope which runs from the hoist drum of a crane or derrick, through sheaves on the bucket, to a closing arm which pulls the halves of the bucket together. A latched arm holds bucket closed; it is tripped open by a hand line. It is not possible to lower a single-line bucket to a pile and then dump or discharge a part of its contents.

Electric Motor Buckets. The Hayward electric motor bucket differs from all others. It uses an electric motor with a compact geared hoist in the upper head. Winding up a chain raises the lower head and closes the bucket; reversing the motor opens the bucket. A slip clutch prevents overload on the motor if the current is not cut off when the bucket is closed. Current is supplied through a flexible cable, which, when the travel is considerable, is automatically wound and unwound from a drum operated by an internal coiled spring, and with collector rings on the end of its axle. An electric controller, hand-operated, starts, stops, or reverses the motor to close, hold, or open the bucket. This bucket can be hung on a single hoisting rope, or from the hook of a rope tackle used with a single drum, or from the hook of an ordinary hoist or crane.

DRAGLINE BUCKETS (Fig. 6) are used with locomotive cranes or slack-line cableways. The bucket is an open-end box with a digging lip, with or without teeth. The dragline is hitched by a pair of chain bridles with clevis connections to front of bucket. When used with a locomotive crane, the bucket is pulled into dumping position by a line from one of the drums over the end of the boom, and hitched to the back end of bucket. In the slack cable system, the bucket, hung from the carriage, runs up the track cable with a traveler block, hits a stop button;

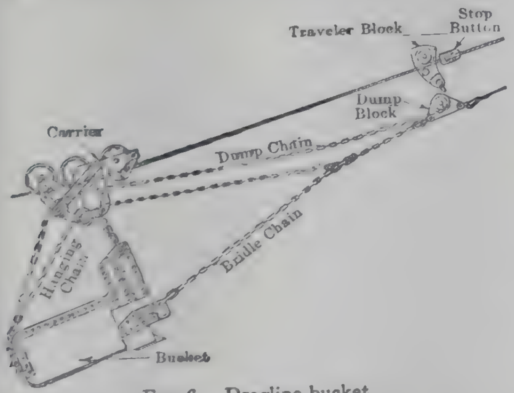

Fig. 6. Dragline bucket.

further motion of the hauling rope pulls on the dump chain hitched to back of bucket. (See Fig. 6.)

6. LIFTING MAGNETS

LIFTING MAGNETS are used with bridge cranes, monorail carriers, locomotive cranes, and derricks to handle iron and steel of all kinds, sizes, and shapes, hot or cold. In general the only labor needed is that of the crane man, who operates both crane motor and the magnet controllers. A magnet, in combination with a bridge crane, can pile steel higher and more compactly than any other means; cars can be unloaded more quickly and demurrage avoided; magnets will handle steel hot from the roll and will work under water.

A lifting magnet consists of a circular or rectangular cast-steel case enclosing copper coils, inner and outer pole shoes to form contact with the material lifted, and a nonmagnetic shield to protect the coils from the material. Rectangular magnets have less lifting power than circular magnets. They lift only what they actually touch, but round magnets will operate through an air gap of 5 to 15 in. according to their size.

Figure 7 is a cross section of a round magnet, and Table 1 gives capacity per lift for different kinds of service for average 10 hr steady work. If service is not continuous, the coils run cooler and the lifting capacity is greater. Figure 8 shows three rectangular magnets hung from a spreader beam for lifting long plates.

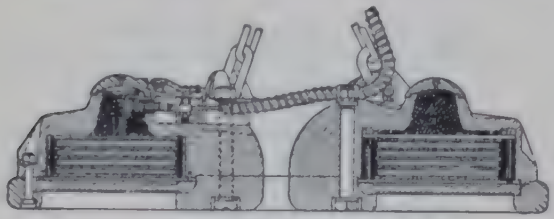

FIG. 7. Lifting magnet.

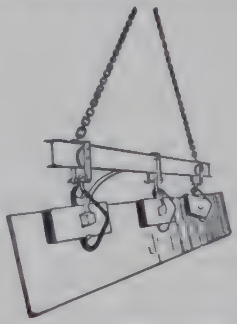

FIG. 8. Lifting magnet, handling long plates.

To provide direct current needed for a magnet, locomotive cranes are fitted with a generating set in the cab. On a-c bridge cranes, a motor-generator set on a platform over the operator's cage supplies direct current. The trolley has a cable winding drum for taking up or paying out electric cable to the magnet.

Table 1. Average Lift, Pounds, for All-day Service of Lifting Magnets

(Courtesy of Cutler-Hammer, Milwaukee, Wis.)

Size of magnet, in. diam.*	65	55	45	39	24
Skull cracker balls	40,000	30,000	24,000	18,000	6000
Slabs	60,000	50,000	35,000	20,000	6500
Machine-cast pig from cars	2,800	2,280	1,275	750	250
Sand-cast pig from cars	2,650	2,170	1,150	680	225
Broken scrap	1,800	1,300	1,000	600	200
Cast-iron borings	2,300	1,500	1,100	600	200
Steel turnings	1,100	750	450	300	100
Principal uses	Large capacity; heavy duty	Open-hearth plants; steel mills	General work; larger capacity with locomotive cranes	Pig iron; scrap; medium capacity with locomotive cranes	Light-finished parts; pipe; castings

* Round magnets 18 in., 12 in., 7 in., 5 in. in diameter also are made.

Round magnets often are hung over a belt conveyor to remove stray iron from coal, foundry sand, etc., carried on the belt. The diameter of the magnet should be one-third larger than the belt width, and it should not be higher above the belt than one-fourth the belt width. Belt speed should not exceed 450 ft per min.

CRANES AND DERRICKS

A hoist is a machine for raising and lowering loads. A crane is a hoist or number of hoists so mounted as to move loads both vertically and in other directions.

SAFETY STANDARDS FOR CRANES, DERRICKS, AND HOISTS. The safety code sponsored by the ASME and ASA defines terms, states requirements of design and construction, and gives rules to promote safety in operating.

Cranes generally are tested by their makers with a load 25% greater than the load for which they are rated.

7. TYPES OF CRANES

Cranes which lift and swing the load are pillar cranes, jib cranes in various forms, derricks, rotary bridge cranes, locomotive cranes. Cranes which lift the load and travel with it comprise many forms of bridge and gantry cranes.

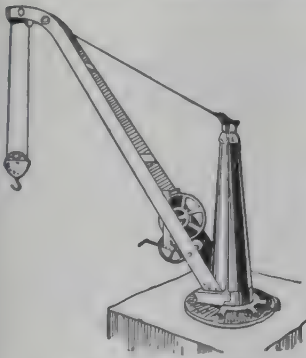

FIG. 1. Pillar crane.

A PILLAR CRANE consists of a stiff self-supported column, turning on a vertical axis and fitted with an inclined boom, the end of which carries the load. The boom swings in a full circle on ball or roller bearings. Hoisting is by hand-power winch on the column. Figure 1 shows a type made in sizes of 2 to 20 tons; working radius 12, 15, or 20 ft.

Pillar jib cranes have a trolley traveling on a horizontal boom to carry the load. The hoist is hand or power; the trolley usually is moved by hand. The jib may be two channels or a single I beam for chain, electric, or air hoist. (See Fig. 2.)

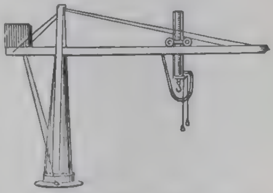

FIG 2. Pillar jib crane.

TOP-SUPPORTED JIB CRANES require the top of the column to be braced to a wall or ceiling, or by guy ropes or struts. They include yard derricks, foundry cranes, and sidewall cranes for machine shops. Figure 3 shows one with separate hand winches for hoist and traverse. Jib cranes sometimes are made with single I-beam jib for hoists hung from four-wheel trolleys as auxiliaries to traveling bridge cranes.

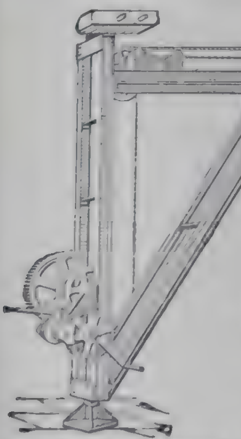

FIG. 3. Top-supported jib crane.

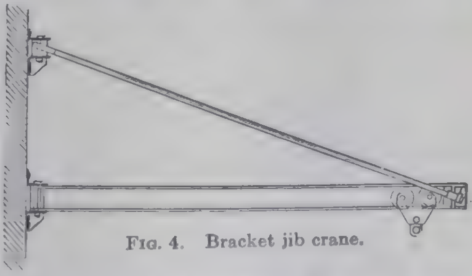

FIG. 4. Bracket jib crane.

PORTABLE JIB CRANES can be made to serve different areas of shop floor as needed, by fitting building columns with socket connections to fit loose-pin connections on the crane mast.

BRACKET JIB CRANES have a horizontal jib hinged to a wall bracket by a vertical pin, and stayed by a rod hinged to an upper bracket. The form shown in Fig. 4 has an I-beam jib for a trolley, from which hangs a hand or power hoist. Bracket jib cranes also are made with built-up girder rail jibs for monorail. (See p. 26-28.) The ends of the special rail on the jib can be fitted with interlocks to engage with fixed tramrail. Trolleys on the jib thus also may run on tramrails radiating from the bracket crane, and serve a large area. To serve trolley tracks running through a doorway, bracket jib cranes are made hinged to lie flat against the wall and allow the door to close.

WALKING CRANES and **traveling wall cranes** are jib cranes mounted for longitudinal travel, the first runs on a track on the shop floor with an upper rail on the wall or building columns to take the thrust at the top of the mast. The wall crane (Fig. 5) has an upper and a lower thrust track on which run flat-faced rollers, while the vertical load is taken on a separate rail mounted on wall brackets. The thrust load is much greater than the dead load when the trolley is at the extreme end of the crane. Such cranes act as auxiliaries to shop bridge cranes in serving long lines of machine tools or in handling riveters on long structural steelwork.

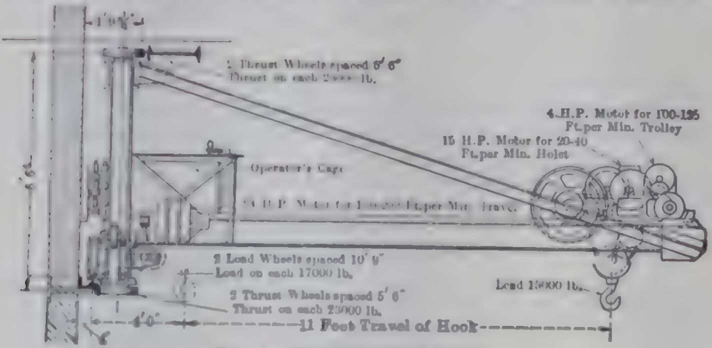

Fig. 5. Traveling wall crane.

GUY DERRICKS have a mast, with a step and vertical pivot pin, at the base, a boom hinged to the foot of the mast, whose inclination can be varied by rope tackle joining tops of boom and mast. A pivot pin on top of the mast fits a cap to which guy ropes are attached. For hand operation, a double-drum winch is mounted at the base of the mast for hoisting and luffing respectively. If angle of boom is not often changed, a single-drum winch will suffice, luffing being by a hand line hitched to the mast. Figure 6 shows a guy derrick used in quarries and by contractors in bridge and building construction. It is operated by steam or power hoist with two hoisting drums for load and luffing, and a pair of swinging drums. Ropes from the latter lead to opposite sides of a bullwheel, on the foot of the mast, to swing mast and boom. The luffing rope runs to foot of mast, to masthead, thence to tackle between masthead and top of boom. The hoisting rope follows a similar path, and runs through sheaves on the boom to the suspended load. Stress in boom-hoist tackle increases as boom is lowered. Hoisting rope is generally 6 by 19 steel wire rope; boom hoist line is the same, but with more parts in the tackle. Stresses in guy lines can be calculated from their arrangement around the mast with respect to the position of the load and also with respect to the angle they make with the horizontal. For other points on derrick design, see Ref. 1. Contractors' derricks often are made of steel for safety, and in sections for ease in handling.

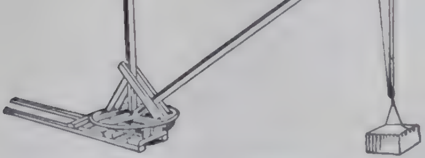

Fig. 6. Guy derrick.

STIFF-LEG DERRICKS are used where it is not feasible to run guy ropes, or where derrick must be shifted often. (See Fig. 7.) Struts from masthead, inclined at 45 degrees, are framed, or hinged, to two sills set on the ground at 90 degrees, meeting under the step of the mast. The boom can swing 270 degrees. Sills can be bolted to foundations or held down by weights.

JINNIWINK DERRICKS are similar to stiff-leg derricks. An A frame replaces the mast, and with its back strut is mounted on a T-shaped frame acting as a base. The boom, hinged to the base frame, is adjustable for angle. These derricks, light and easily set up, are used by building contractors.

TOWER DERRICKS consist of a square tower of wood or steel with footings for booms on one or more corner posts. They are used in building construction, booms being shifted higher on the posts as the building goes up. A steel tower derrick with a revolving pivoted counterweighted 50-ft boom is used in building construction in Germany. It will lift 1 ton with boom horizontal; maximum height of lift with boom luffed, 100 ft. The tower rests on a wheeled platform, and has three small electric winches, controlled by a man on the platform.

The concrete distributing apparatus (Fig. 8) is a modified mast and tower derrick. The mast hoist has a framed steel mast, about 20 in. square, made in 20-ft sections with bolted end connections and guy attachments. It has guides for a dump bucket which discharges into a receiving hopper adjustable in height on the mast, from which chutes distribute concrete. The upper end of the chute is a boom, guyed from the mast head. Extensions of the chute hang from trolleys on a chute-extension cable which spans the area over which concrete is distributed. Figure 8 shows a 60-ft mast with a 40-ft boom chute, served by a 1-yd hoist bucket. Larger plants have steel or wood guyed towers, with one or two hoist buckets. Masts and towers for this system of distributing concrete have been designed and standardized for rapid and easy erection.

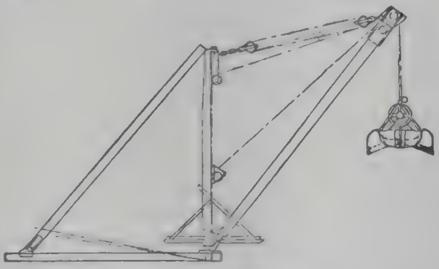

Fig. 7. Stiff-leg derrick.

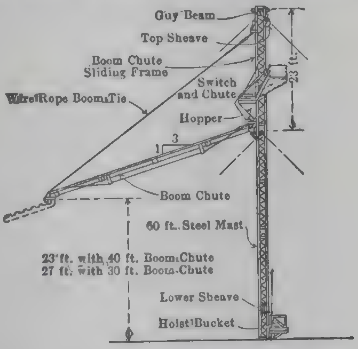

Fig. 8. Tower derrick and boom chute. (Insley Manufacturing Co., Indianapolis, Ind.)

TRAVELING BRIDGE CRANES. Makers of tramrail equipment (see p. 26-28) list and illustrate in their bulletins a wide variety of light cranes for 2 tons or less load. Table 1 classifies Cleveland tramrail bridge cranes; similar cranes are made for American monorail. These light cranes are notable for several reasons. (1) End trucks have equalizer levers and swivel wheels; wheel flanges do not bind on the rail. (2) Structure is light; wheels have ball bearings; crane is easy to move. (3) The light construction of bridge, flexible mounting of the wheels, and absence of a squaring shaft permit cranes to be hung from three runways if bridge is longer than 30 or 35 ft. By using three runways weight of the bridge can be kept so low that a 50-ton crane can be moved by pushing or pulling the load, and there is no danger of pinching or binding the runway. (4) Most types can be fitted with interlocks to register bridge rails with fixed tramrail, so that hoists, carriers, and trailers can travel on or off crane bridge. (5) Electrical conductors and mountings, control, and accessories are well standardized. (See Fig. 9.)

Table 1. Cleveland Tramrail Bridge Cranes

(Courtesy of Cleveland Crane and Engineering Co., Wickliffe, Ohio)

Bridges Propelled by Hand (Pull or Push Load)

Type CH: For any Cleveland carrier or hoist, hand or electric up to 2 tons capacity; 2 runways for bridge lengths up to 30 ft.; 30 to 50 ft. 3 runways.

Type CHL: For any Cleveland carrier or hoist, hand or electric, up to 2 tons capacity; 2 runways for bridge lengths up to 30 ft.; low headroom.

Type DGH: Double girder bridge; trolley hoist on top. Capacities up to 1 ton; 2 runways for bridge lengths up to 30 ft.; low headroom.

Bridges Propelled by 2 or 3 Motors

Type UCE: For any Cleveland carrier or hoist, hand or electric up to 2 tons capacity, 2 runways for bridge length up to 30 ft.; for 30 to 50 ft. 3 runways.

Type DGE: Double girder bridge; hand pushed trolley; capacities up to 2 tons; 2 runways for bridge lengths up to 30 ft.; low headroom.

Type DGEE: Same as DGE except that trolley is motor-driven.

Type DGC: Like DGEE, but operator controls all motions from cab mounted on bridge.

Other bridge cranes, for loads up to 5 tons and for spans under 30 ft, are made of single I-beam spans with trolley hoists hung from lower flanges. The bridge travel of these cranes is generally by hand chain hung from a chain wheel on a squaring shaft that drives truck wheels at each end of the span. For loads over 3 tons, it is better to have a gear reduction between chain gear and squaring shafts.

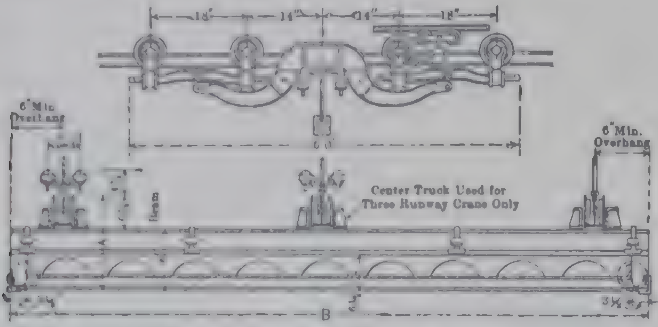

FIG. 9. Cleveland Tramrail crane.

Double I-beam cranes are used for loads up to 20 tons and for spans of 20 to 50 ft. The trolley runs on top of the girders. The hoist rope is wound on a drum which may be geared to hoist light loads at faster speed than heavy loads. With double I-beams, the load hook can go between the beams, and for a given lift, the building need not be so high as it would be if trolleys were hung below the beam. Some cranes have two trolleys for handling long or heavy pieces.

The hand-power cranes mentioned are for what crane builders call class D, i.e., very intermittent, service. If hand operation is too slow, I-beam cranes can be fitted with one or two motors (class C service), or with three motors for class B service, which means the ordinary work of a crane in shops, foundries, yards, etc., where the crane is busy 8 or 10 hr and adjustments, inspections, and repairs can be made in idle time.

A three-motor bridge crane for class B service is shown in Fig. 10. The bridge is made of two I-beams to carry the load, with two light lattice-girders to stiffen the frame and to help carry the travel machinery. The bridge often can be shipped and erected as a unit. The trolley frame is a one-piece steel casting; the double-flanged trolley wheels run on flat bars welded to top flanges of the girder beam.

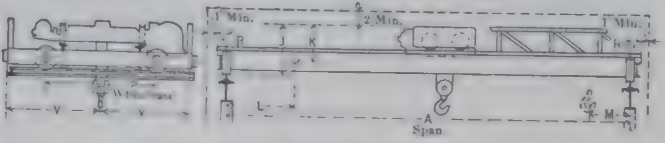

FIG. 10. Light-duty bridge crane.

Cranes for class A service work 24 hr a day in steel mills, cement mills, and foundries, or on heavy hoist and grab bucket or magnet work, where interruption of service is serious. (See Fig. 11.) Speeds of hoists, trolley, and travel often are higher than for cranes in lighter service; motors are larger; parts are designed with a higher factor of safety and with more regard to access to working parts and certainty of lubrication. Cranes made by various makers do not differ much in essential dimensions.

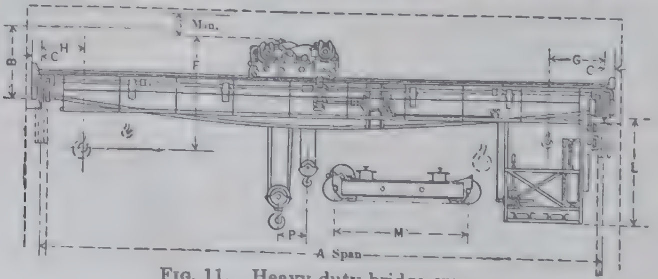

FIG. 11. Heavy-duty bridge crane.

AUXILIARY HOISTS FOR CRANES. The dimensions P and G in Fig. 11 for cranes over 10 tons refer to position of hook of the auxiliary hoist, which is used for rapid hoisting of loads lighter than those for which the crane is designed. For this duty the trolley carries two motors, each with its own set of drums and gearing. One set is for the main hoist of the rated capacity of the crane; the other is for 3, 5, or 10 tons auxiliary capacity.

CRANES FOR OPERATING GRAB BUCKETS for handling coal at power plants, raw material and clinker at cement plants, unloading bulk material from cars, etc., have a trolley with two drums, one for closing line and one for holding line. The drums are mounted parallel to the bridge girders; each has its own motor, solenoid brake, and reduction gearing. If the crane does miscellaneous hoisting and a bucket is used only occasionally, the trolley can be of the ordinary hoisting type, and the bucket of the single-line or one of the motor-driven types, to be put on the hook block when needed.

Grab bucket cranes are made by most builders of heavy-type bridge or gantry cranes. Dimensions of trolley vary with weight and type of grab bucket and height of lift. Parts generally are of heavy construction, and precautions are taken to keep dust out of gears. All motions of crane and bucket are electrically controlled from the operator's cab, usually mounted on the trolley.

TRENDS IN CRANE DESIGN (Ref. 2). Modern cranes are characterized by less dead weight, by rolled beams instead of box girders, lighter motors, alloy steel parts, ball or roller bearings, heat-treated gears, gears enclosed for protection and running in oil baths, grease cups, and intermittent oiling being avoided. Bridge cranes with structural parts of aluminum alloy are described in Ref. 3. Advantages claimed are reduction of weight, less power for travel motions, and no necessity of painting.

GANTRY CRANES. For loads up to 2 tons Cleveland tramrail can be fitted to two gantry legs. (See Fig. 12.) All wheels have ball bearings, and the structure, with load, can be moved by one man at either end pushing or pulling. For rapid or long travel the crane can be electrically propelled. These cranes can be used in shops as auxiliaries to traveling bridge cranes. Cleveland gantry cranes can be interlocked to register bridge rails with fixed tramrail so that hoists, carriers, and trailers can move on and off the gantry bridge.

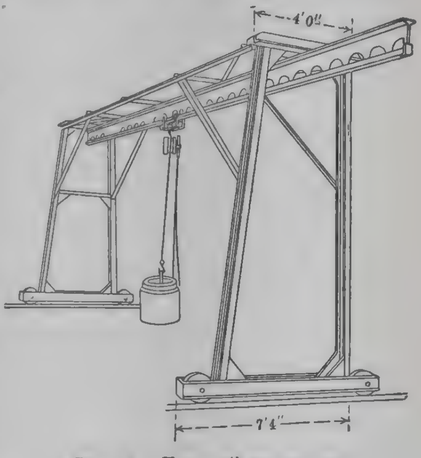

Fig. 12. Tramrail gantry crane.

Gantry cranes of heavier type range in size from 5 to 250 tons capacity, of any span. In construction they are like bridge cranes built for hoist, bucket, or magnet work, but have better protection from weather for operator and machinery. For travel motion, power is transmitted from a motor on the bridge through horizontal and vertical shafts to geared truck wheels at ground level. Truck should have brakes to prevent high winds moving the bridge. Such mechanical and electrical brakes are described in Ref. 4. If the crane serves a yard alongside a building, it is sometimes convenient and economical to support one crane track on the building wall. The crane is then a *single-leg gantry.*

The advantages of gantry cranes are that there is no expense for overhead runways; tracks can be extended or changed in position; and there is no obstruction of yards by overhead track supports.

Portal cranes (double-leg) or **semi-portal** cranes, single-leg, are similar to gantry cranes. They generally have a rotating crane or a crane with luffing motion mounted on top of the structure to transfer freight from ship to wharf or vice versa.

SPECIAL CRANES FOR STEEL WORK. **Ladle cranes** are made up to 300 ton capacity to control all the motions of filling, transporting, and pouring hot-metal ladles in open-hearth plants. They have two independent trolleys with a pair of girders for each. The main trolley travels on the outer girders and hoists the ladle; the auxiliary trolley travels on the inner girder and has two hoists to tilt the ladle one way or the other. To insure safety, the two hoist motors and two sets of hoisting machinery are geared together to prevent the ladle from tipping sidewise and spilling metal if one motor or set of gears should fail.

Ingot-stripping cranes are of several types. In one, a vertical arm suspended from a trolley carries jaws which seize the hooks of the ingot mold, while a screw-actuated plunger pushes the ingot from the mold. Some cranes carry auxiliary trolleys to handle stripped ingots. In rope-operated cranes, the hoist block carries tongs which lift the mold while a stationary ram pushes the ingot out.

Soaking-pit cranes do all the work of handling ingots into and out of soaking pits. In one type, a trolley carries a guided vertical ram, gear-operated, with gripper jaws on the lower end. These have an automatic closing motion, suitable to ingots of different widths. The ram rotates on a vertical axis. This type requires high headroom. Rope-operated types require less headroom, have a shorter ram, and the guides are below the trolley.

Crane-type Charging Machines. A vertical frame moves with the trolley and is braced against the underside of the bridge girders. It carries an arm that holds the charging box and turns it over when it has been pushed into the open-hearth furnace.

ELECTRICAL EQUIPMENT FOR OVERHEAD CRANES. Alternating current generally is used for most cranes. More delicate control can be obtained than with direct current, especially for light loads. If both alternating and direct current are available, choose alternating; if only direct current, do not convert it to alternating, but use it.

OPERATING SPEEDS OF CRANES. Table 2 shows motor sizes and operating speeds of shop cranes in intermittent service. For heavy-duty and 24-hr service, heavier motors and higher speeds generally are used. High speeds of hoist and travel cannot be attained in short movements, because much of the time is used in accelerating and decelerating moving parts. (See p. 26-21.) In estimating capacity of a crane to hoist and transfer loads, allowance must be made for time thus lost. For short travel, as in transferring loads from car to adjacent storage, the allowance may be 25% or more.

Table 2. Light-duty Crane Ratings

Capacity, tons	Full Load Speeds, ft per min			Horsepower of Motors			Diameter of Rope, in.
	Hoist	Trolley	Bridge	Hoist	Trolley	Bridge	
1	42	110	175	3	3/4	3	1/4
2	35	110	175	5	3/4	3	1/4
3	33	110	175	7 1/2	1	3	3/8
3 1/2	28	110	175	7 1/2	1	3	3/8
5	26	110	175	10	1	3	3/8
7 1/2	24	110	175	15	2	5	9/16
10	18	110	175	15	2	5	9/16

CRANE SUPPORTS. Running rails are furnished by the user; size is recommended by the maker for the particular service. They must be laid straight and at exact center-to-center distance. Track supports should be strong enough to carry maximum load close to one end of bridge, and stiff enough laterally to take the shock of sudden stops of the loaded crane trolley. Column connections and columns must be designed on a basis of maximum loads. It is well to consult crane builders before design of the building has gone too far.

HOISTING ROPES are cast-steel wire rope, usually 6 by 37, but 6 by 19 and 8 by 19 also are used. Sheave and drum diameter should be (30 × rope diameter). For use of wire rope, see p. 26-02.

8. POWER REQUIRED TO DRIVE CRANES

POWER REQUIRED TO DRIVE CRANES.* The current for hoisting is expended partly in lifting the load and partly in losses in the motor, the solenoid brake, the hoisting gearing and bearings, and the friction and bending of the ropes on the drums and sheaves. As a rough average for shop cranes, these current expenditures may be 70% useful work and the losses 14, 1, 12, and 3%, respectively, of the total current furnished. The size of the motor is determined by the torque required to lift the load plus the torque necessary to bring the load and all the rotating mechanism up to speed in the time allowed by the designer for the hoist to attain its full speed. The overload torque required for acceleration to a speed v in t seconds varies as $1/t$, and that factor, rather than the torque for direct lift, determines the size of the motor in all hoists except very slow ones. In a typical crane hoist (Fig. 13) the effect of the acceleration of all the moving parts on the torque of the motor can be obtained by calculating the weight and radius of gyration of the moving parts at the drum shaft and on all other rotating shafts, and then finding an equivalent weight which, at the center of gyration of the motor armature, will produce the same energy effect.

---

* Adapted from *Electric Crane Construction*, by C. W. Hill, C. Griffin and Co., Ltd., London, 1911.

PRACTICAL RULES. Builders of traveling electric cranes used in shops assume a hoisting efficiency of about 70%, which corresponds to 23,000 ft-lb per min per hp of motor rating. For cranes used in steel mills, grab-bucket hoisting, etc., subjected to occasional overload and rough handling 20,000 ft-lb per min per hp is used. The margin of 30 or 40% generally is considered sufficient to allow for acceleration and for electrical and mechanical losses, but for high hoisting speeds and quick acceleration, the forces due to acceleration should be calculated and allowance made for them.

For travel speeds not over 250 ft per min a rule used in practice is

$$\text{Motor horsepower} = 2\left[\left(W \times \frac{d}{D} \times 0.07 \times 1.07^n \times S\right) \div 33{,}000\right] \qquad (1)$$

where W = weight of loaded crane, pounds; d = diameter of truck axles, inches; D = diameter of truck wheels, inches; 0.07 = coefficient of axle friction, and also is the loss at each cut gear reduction, including journal friction of countershaft; n = number of gear reductions; S = speed, feet per minute. The factor 2 covers overload due to acceleration, bad condition of crane track, "notching-up" controller too rapidly, etc. For greater safety against these adverse conditions, the factor sometimes is made 2 1/2. For speeds over 250 ft per min and for quick acceleration, the forces due to acceleration should be calculated and allowed for.

The following rules are given in Ref. 5: Horsepower of hoist motor = (Load in tons × Lifting speed, feet per minute) 11. This is equivalent to assuming an overall efficiency of 66%. Horsepower of trolley motor or bridge motor = $(WS/132)(d/D)$, if bearings are bronze bushed; or $SW[30 + (S/20)]/33{,}000$, if axles run in roller bearings. In these equations, W = total weight moved, tons; S = travel speed, feet per minute; d = diameter of axle, inches; D = diameter of wheel, inches.

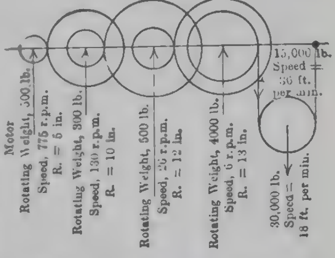

FIG. 13. Diagram of crane hoist speeds.

9. LOADING AND UNLOADING EQUIPMENT

ORE BRIDGES AND COAL-STORAGE BRIDGES are gantry cranes with a grab bucket to take ore or coal from boats, cars, or a dump to storage, and to reclaim it from storage to cars or boats. As used at Great Lakes ports, these often are bridges spanning 300 ft or more over the storage area, with cantilever extensions over the water at one end and over railroad tracks at the other. In modern bridges up to 10-ton buckets have all drums for control of bucket mounted, together with operator's cab, on the trolley.

In some storage bridges a revolving crane, with a grab bucket on a horizontal boom, runs on the top chords of the bridge. Coal from boats is delivered to a belt conveyor on the bridge and tripped off into storage. In reclaiming from storage, the crane boom swings sideways from the bridge and the grab bucket drops the coal into a hopper delivering to the belt conveyor. Coal can be reclaimed at the rate of 300 tons per hr.

BOAT LOADING. At the upper end of the Great Lakes, over 80 million tons of iron ore are loaded into steamers each year. The ore is dug by steam shovel and loaded into large bottom-dump cars, which at the shipping pier run on high trestles. When the bottom doors open, the ore drops and and runs freely through long chutes into the boat.

On the Atlantic coast, coal is shipped from Norfolk, Baltimore, Philadelphia, and other ports the year round. In winter, it sometimes is necessary to thaw the railroad cars in a closed thawing shed before dumping. At some piers the cars run into a rotary dumper, are turned over, and the coal runs into transfer cars. The transfer cars may be lifted to the top deck of the pier to dump their coal into hoppers and ship-loading chutes, or they may travel along the pier and discharge to a conveyor on a boom extending over the boat. In a plant at Baltimore the turn-over motion of the Wellman rotary dump is so controlled that the coal slides out, without much breakage, to an apron conveyor which in turn discharges to the conveyor on the boom. At the end of the boom a vertical chute with a control gate, to ease the fall, delivers coal to the boat. Boats loading coal at Atlantic ports are of all sorts; hatches generally are small, and chutes must be arranged to suit them and to clear ship's rigging. At a coal pier at Pensacola, Fla., a Link-Belt car dumper feeds two bucket elevators, of 300 tons per hr capacity each. They can discharge at heights variable by 45 ft to suit a great variety of boats and conditions of loading. Loading chutes have telescopic ends and a horizontal swing of 180 degrees.

The large boats bringing ore from the head of the Great Lakes and taking coal back are designed for the purpose. At coal shipping ports, mostly in Ohio, boats are loaded by coal dumpers generally of the lift type. An example is the Link-Belt rolling dumper which pours the contents of a 40-ft car into a barge. When car is empty the cradle runs down an inclined track. For history and description of car dumpers, see Ref. 6.

BOAT UNLOADING. Clam-shell buckets are in general use for unloading boats. For intermittent service and small capacities, a mast and gaff with a clam-shell bucket and 2-drum hoist is good and cheap. An inclined boom (gaff) swings around the mast, the bucket being hung from the top end of the gaff. Guide sheaves for holding and closing lines (see p. 26-13) are spread apart at the heel of the gaff, so that the swing of the gaff toward and from a belt hopper can be controlled by putting more tension on one line than on another by means of clutches and brakes at the hoisting machine. Such hoists are used for boats and barges having no rigging to interfere with the swing of the gaff; for rigged boats a tower with a boom hinged to swing vertically is necessary.

Hoisting towers, with separate hoists to lift the bucket and trolley it on the boom, permit rapid work, as the two motions are simultaneous part of the time. They often work in combination with cable railways or conveying systems to handle coal at storage pockets and power houses on water fronts. To transfer coal or ore from boat to cars or to storage piles, the hinged boom may be a cantilever extension of a bridge tramway.

The Hulett unloader (Wellman Engineering Company) comprises a large gantry frame spanning a number of railroad tracks and carrying a trolley. To the trolley is pivoted a pair of arms carrying a vertical bucket leg. An operator in the leg controls all motions of bucket, trolley, and gantry. A second operator on a traveling scale lorry, hung under the gantry, receives the discharge of the bucket through a hopper holding three bucket loads. After weighing, the larry discharges to railroad cars or to the reserve storage space under the cantilever end of the gantry. Large Hulett buckets spread open to 24 ft pick up 17 tons of iron ore, and make the cycle of load, traverse, and dump in about 50 sec.

FREIGHT HANDLING TO AND FROM SHIP. In the United States ships generally are loaded and unloaded by the ship's own winches and rigging. In Europe most of the work is done by wharf cranes, as much of the freight comes and goes in barges without hoisting machinery. To handle freight to and from ships faster and cheaper than by use of the ship's winches, cargo cranes on the wharf must be kept to that one duty and not be burdened with distribution on the wharf. Monorail hoists and tramrail carriers have been used on a few wharves, but electric or gasoline tractors with trains of trailers are more flexible and useful.

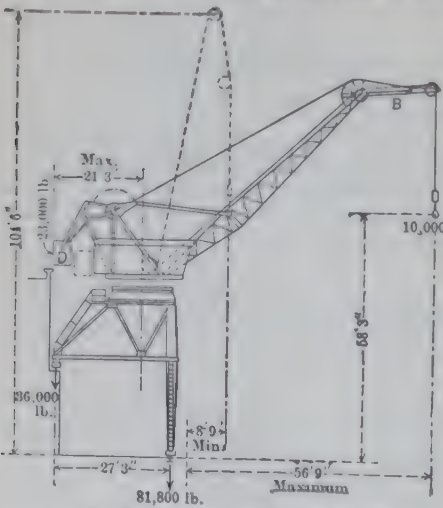

Fig. 14. Level-luffing type of crane.

Most wharf cranes are traveling gantries with a revolving crane on top of the bridge. Crane booms often are rigged with a "level-luffing" device. Figure 14 shows one type. Outrigger *B* and counterweight *D* are mounted so that with hoist drum braked, boom can be moved in a vertical plane without raising or lowering the load. The advantages are that several cranes can work in one hatch without interfering with each other or with the ship's rigging; time is saved; and the boom hoist motor may not be so large. See Bernard Dunell (Ref. 7). For methods of weighing the load on the crane according to the tension in the hoisting line, see Ref. 8.

Cargo cranes generally have a lifting capacity of 10 tons or less, but important European harbors always have some wharves with large cranes to handle heavier loads. A typical hammer-head crane is one that will lift 150 tons from a large ship at a distance of 65 ft from the wharf front, and 80 or 90 ft above the wharf. Heavy lifting also is done by pontoon cranes; they often work from the harbor side of the ship while the wharf cranes work on the other side. A typical 150-ton capacity crane of this kind has a diesel engine power plant for hoists, lighting, and driving the screws which propel the pontoon at a speed of 4 knots. See articles in Refs. 9 and 10.

HOISTS

10. HAND-OPERATED HOISTS

HAND POWER HOISTS (or chain blocks) are made in three types: (1) Differential hoists contain two chain wheels above, cast as one piece, and a single wheel below. An endless chain passes over one upper sheave, down around the bottom wheel that carries the load hook, then up over the other wheel. For theory of this device, see p. 7-17. (2) Screw-geared hoists have a worm gear that holds the suspended load by friction of the thread of the worm. (3) Spur-geared hoists have a train of spur gears with a friction-disk brake of the Weston type to hold the load. (See Fig. 1.) Type 3, when fitted with ball-bearings, will deliver 85% of the work of the operator to the load hook. Its mechanical efficiency is about twice that of a screw-geared hoist and nearly three times that of a differential hoist. (See Table 1.)

Table 2 shows hoisting speeds and pulls on hand chain for the three types of hoist as stated by one maker. Other makers list the same sizes; their dimensions and ratings are nearly the same. The speed of a chain hoist depends on the pull required on the hand chain and number of feet of hand chain overhauled to lift load 1 ft. Speeds given in Table 2 are for short lifts with men accustomed to the work. For easy continuous lifting, use two-thirds of the values given for hoisting speeds. The spur-geared hoist has less internal friction, lifts and lowers load more rapidly than the others. The screw-geared hoist is lighter, takes up less headroom, will work in any position (as for horizontal pulling), and is well suited to work of riggers and repair gangs. The differential hoist is still lighter and serves well for occasional use.

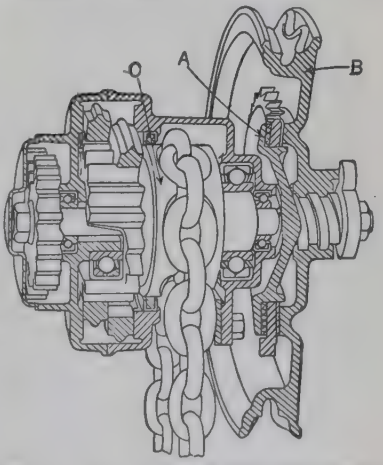

Fig. 1. Spur-geared hoist with friction brake.

Table 1. Comparison of Chain Block Hoists

	Differential	Screw-geared	Spur-geared
Mechanical efficiency	35%	40%	85%
Relative durability	20%	80%	100%
Relative cost	40%	70%	100%

Figure 1 shows the Cyclone hoist made by Chisholm-Moore. Gearing is compact and entirely enclosed in a grease-filled case. Brake wheel *A* is keyed to the shaft that carries hand chain wheel *B*, whose bore is threaded to fit a thread of hub on *A*. The pull of the load chain on wheel *C* acts through the gears to move *B* to the left, squeezing the leather and steel friction rings against *A*. A pawl engages ratchet teeth on the rim of *A*, prevents the latter from turning, and holds load suspended while the friction surfaces are squeezed together. To lift load, *B* is pulled in direction in which ratchet is free, the friction surfaces being engaged. To lower, load *B* is pulled in the opposite direction; it moves on threaded hub of *A* just enough to overcome friction imposed by the load; the pawl engages the ratchet and holds brake wheel when the motion of hand chain stops. This description applies generally to all screw-type brakes (known also as Weston brakes) used on hand-driven or power-driven hoists.

Table 2. Hand-power Chain Hoists

* On each of the two hand chains.

The Cyclone hoist, in sizes up to 2 tons capacity, also is made with aluminum alloy parts. These hoists are one-third lighter than regular hoists, and can be put up and taken down more easily. A safety device throws the hand chain out of gear if the hoists are subjected to an overload more than the 50% excess over normal rating to which they are tested by the maker. Constants for speed and pull are about the same as those given in Table 2.

If it is not convenient for the operator to stand under the hoist, a fixed winch operated by a hand wheel or by a hand chain may be used. (See Fig. 2.) The mechanism is that of a chain hoist enclosed in a box that can be bolted to a wall, building post, or mast of a jib crane. These hoists, up to 2 tons capacity, are listed by several makers.

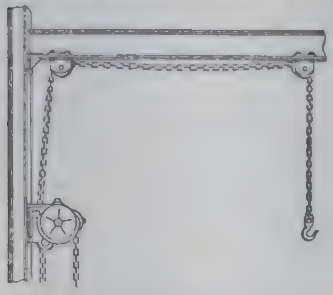

Fig. 2. Spur-geared hand winch.

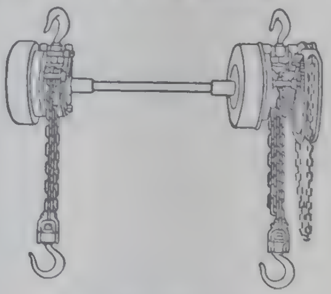

Fig. 3. Twin hook chain block.

Hoist makers furnish double hoists (Fig. 3) for lifting lumber, tanks, platforms, truck bodies, etc. They are made in sizes up to 10 tons, and with hoists spaced to suit dimensions of pieces handled. Four- or eight-wheel carriers with double hoists hooked on, or built in, are listed by some builders of tramrail systems.

The usefulness of a hand hoist can be increased if it is hung from a trolley on an overhead track. If the track forms the bridge of a traveling crane or is attached to a jib crane, a greater area can be covered. These trolleys are moved by moving the load or are geared and propelled by a hand chain. The Ace geared trolley (Robbins & Myers) is shown in Fig. 4. It has cast-steel side frames with adjustable spacing for track beams of different widths. The load wheels have no flanges; guiding is done by small rollers which bear against lower flanges of the beam. Similar geared trolleys are furnished by other makers of hoists. Trolleys with four or eight ball-bearing wheels, not geared, are made to take standard makes of chain hoists up to 2 tons capacity, to run on American monorail or Cleveland tramrail tracks. (See Fig. 5.)

The so-called Army type of chain hoist is a combination of a trolley, either geared or plain, with the hoist mechanism built in. The advantage is that the load hook can come closer to the bottom of the I-beam track. The disadvantage is that the hoist does not work so well if the pull of the load is much off to the side of the track. Figure 6 shows a hoist of this type, the "Rail Hugger" (Yale & Towne). The hoist is spur geared with ball bearings; the trolley frame is steel plate; the chilled wheels have roller bearings.

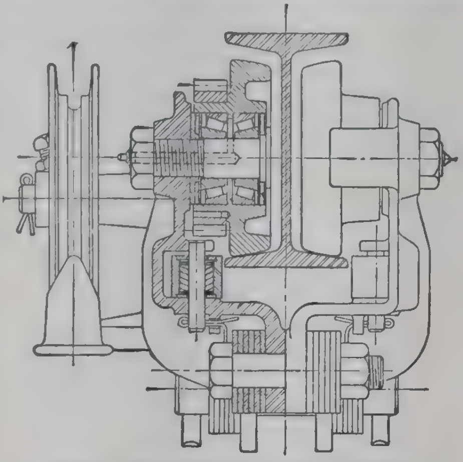

Fig. 4. Geared trolley for hand hoist.

TRACKS FOR HOISTS. Standard I beams are in general use to carry trolleys of hoists, especially for heavy loads. The beams should be straight; where they join, the bottom flanges should be supported by a plate, otherwise the corners may be bent down by the trolley wheels. It is not usual to splice webs. Supports or hangers are fastened to top flange in various ways to leave room for trolleys. Under frequent passage of heavy loads, lower flanges tend to bend down from peening action of the wheels. This can be prevented by riveting strips to lower flanges to act as a track. The double-rail construction in Fig. 7 serves the same purpose. The I-beam track made by Richards-Wilcox Company, Aurora, Ill., consists of straightened beams; Fig. 8 shows a joint and Fig. 9 an I-beam switch. Pulling the hand chain releases a latch pin, then draws the movable beam over to the next position. A guard plate keeps the trolley from running off the open end of tracks not in register.

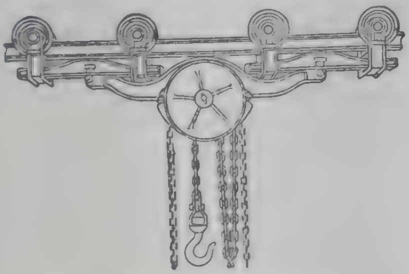

Fig. 5. Tramrail chain hoist carrier.

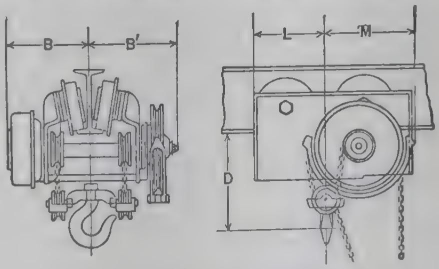

Fig. 6. Army-type chain hoist.

Similar track work is made by Philadelphia Tramrail Company, Philadelphia, and some builders of hoists. See also Tramrail Systems, p. 26-28.

PORTABLE HOISTS of the type shown in Fig. 10 are made for loads up to 3 tons. They serve where it is not convenient to hang up a chain hoist. Lifting is by a winch built in the frame, or a chain hoist hung from top of the column.

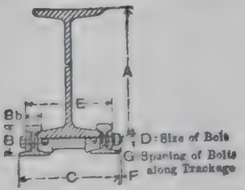

Fig. 7. Double rail boist track.

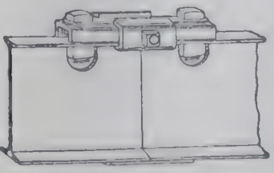

Fig. 8. I-beam track joint.

SPUR-GEAR HOISTS in capacities up to 1 ton, operated by hand rope or hand wheel, and fitted with automatic stops and safety devices, are available. They are fitted with platforms or containers for hoisting or lowering from floor to floor or from sidewalk to basement. These machines are also made with electric motor drive.

Small hand-operated counterbalanced hoists for carrying parcels, tools, and books rapidly from floor to floor are available. In some cases, installation of these machines is subject to State Elevator Codes and local regulations in regard to safety and fire.

CRABS OR HAND WINCHES are made as self-contained units for use with derricks, with block and tackle for riggers, or for lifting through heights beyond the range of chain blocks. In the portable form, hand winches consist of two frames carrying a drum with, usually, two sets of gears on shafts with squared ends for the cranks. Sometimes drum shafts also are squared, to allow slack rope to be taken up quickly by using cranks directly on the drum. One pinion is made to shift in and out of gear, so that cranks can be used on either pinion shaft for different hoist speeds. The load is held and controlled for lowering either by a ratchet and pawl, by a strap brake, or by a friction disk brake of the Weston type. The friction brake will prevent the cranks from accidentally flying back and injuring workmen, as often happens with crabs equipped only with ratchet and pawl. The principle of the Weston brake is shown in Fig. 1. The same mechanism frequently is fitted to flat frames for use on masts of jib cranes and derricks. Simple worm-geared winches of a capacity of 1 ton or less are made by nearly all makers of conveying machinery.

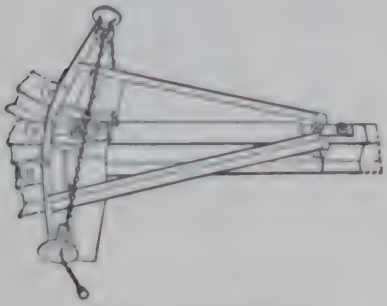

Fig. 9. I-beam switch.

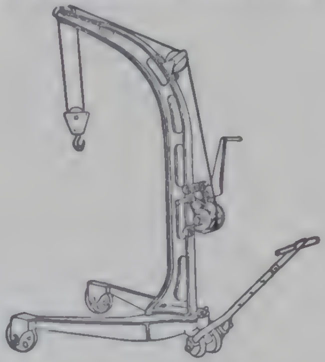

Fig. 10. Portable hoist.

11. ELECTRIC HOISTS

ELECTRIC HOISTS generally use ball and roller bearings, alloy steels, and heat-treated parts. Pressed steel has been substituted for castings in some designs. Welding has replaced bolting in many cases. Motors usually are enclosed, ball bearing, and specially designed for hoist work; high-torque squirrel-cage induction motors are more general than d-c motors. The latter are useful for close control of load movement. Both rope and push-button control are used. Push buttons give quicker, safer, and more convenient control. Electric hoists range in size from $^1/_8$ to 6 tons, with a wide range of hoist speeds. They are made in floor-operated and cab-operated types. For single-speed hoisting, push-button control is the most convenient; one hand is free to steady or guide the load, operation is faster, and the load can be placed more accurately. Cab-controlled hoists are used to transport loads over a considerable distance, where the operator must observe the load from above, or where rapid transfer is necessary.

Worm-driven electric hoists hold the load by friction on the worm thread. Spur-geared hoists use a screw brake (Weston) to hold the load. (See Fig. 1.) All have a limit switch, to prevent overtravel of hoist hook at top of the lift, and a motor brake to stop the rotor if current fails, and to prevent drifting when controller is in "off" position.

In electric chain hoists a chain drive from the motor operates gearing like that in a chain hoist. The load is lifted by a chain driven by a pocket wheel; slack chain is paid out as load ascends. For high lift and for pulling at loads not directly underneath, a chain hoist often is preferable to a rope hoist. Chain hoists are made in sizes of $^1/_8$ to 2 tons.

SPUR-GEARED HOISTS. Figure 11 shows a hoist built in sizes up to 2 tons. The size of main frame determines distance from overhead track to upper position of hook. It is of steel plate with welded joints, and holds drum, drum shaft, and motor brake. Motor and controller are bolted to one side, and an oiltight case with spur gears and brake to the other. All shafts have roller bearings, and all load-carrying parts are steel.

WORM GEAR HOISTS are made in sizes up to 6 tons. In this type a hardened steel worm works in a bronze worm wheel. The thread angle is low enough to make the gears self-locking, thus avoiding a mechanical brake. Some hoists have, beside the worm gears, a pair of spur gears to get greater speed reduction between motor and hoist drum. For foundry work, the worm gear hoist can be fitted with special control. A nonspring-return controller used with an oversized motor gives a speed range of $^1/_{10}$ to full speed, which is useful in handling flasks and molds. A jointed control rod worked by one hand permits operator to use the other hand to guide the load.

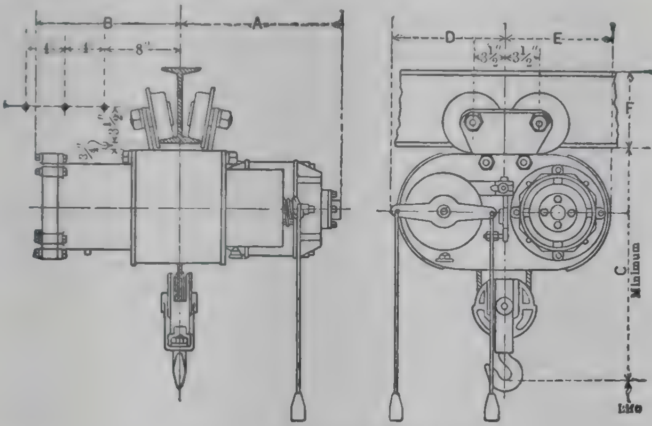

FIG. 11. 2-ton spur-geared hoist.

HOIST CARRIERS. Hoists with top hook or clevis may be used as fixed hoists or attached to a commercial trolley. More headroom is required than when trolley and hoist are combined, and wiring is less neat. Most electric hoists can be made with top connections to fasten to an eight-wheel push-type trolley, which is strong, light, and can pass curves of small radius. Figure 5 is typical; overall length is 66 in.; distance bottom of rail to hook, 21 in.

Plain push-type trolleys for I-beam tracks are useful for moderate distances. If load or hook hangs out of reach, or must be spotted accurately, it is better to use a hand-chain geared trolley. If the hoist must travel much, or if the loads are hot, heavy, or bulky, the trolley can be electrically motor driven. The control cords may be kept away from the hoist by carrying the controller on a separate trolley when the hoist operates through a wide hatchway, from vats or beyond the edge of a platform.

Electric hoists up to 2 tons capacity especially for use with Cleveland tramrail are mounted on four-wheel hand-propelled carriers for 500-lb hoists, and eight-wheel carriers for 1- or 2-ton hoists. An electrically propelled carrier mounted with an electric hoist coupled to a trailing operator's platform has dimensions: Maximum overall length, with single motor drive, 12 ft 3 in.; operator's platform to bottom of rail, 6 ft 11 in. minimum; hook to bottom of rail, 29 in. Carriers also are made for pendant cord control, and also with enclosed operating cab. Travel speeds are up to 600 ft per min, and the carrier can climb grades, run through switches, and pass short radius curves. Most builders supply cab-operated machines to travel in single I-beam tracks. For heavy loads and high speeds, the double T-rail track, shown in Fig. 7, is preferable to the lower flange of the I beam.

TELPHER HOISTS. In Europe, the track rail for outdoor work usually is a T rail on a longitudinal supporting beam. The traveling frame, with cab and hoist or grab bucket, hangs from the trolleys by hook-shaped hangers which permit some side swing. In England, this is known as the Telpher system. A German monorail carrier of this type has no operator but runs instead under an automatic block-control system. Cab control, however, permits higher traveling speed, requires fewer cars, and has less apparatus to maintain.

ELECTRIC CONDUCTORS AND COLLECTORS. If travel of hoist is short, a flexible cable can be supported so as to allow the necessary movement. If cable drags or interferes, a spring-actuated reel can pay out and take up cable automatically. For long travel, shoe or wheel collectors bear against conductors. These may be copper wire, angle iron, flat bar on edge, or an 8-shaped bar. Figure 12 shows the latter with an I-beam track, and Fig. 13 a special track and conductor support made for Cleveland tramrail.

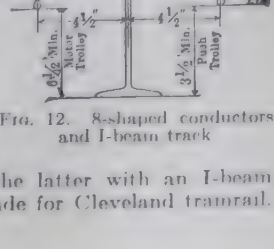

FIG. 12. 8-shaped conductors and I-beam track

The American monorail (see below) uses small channel conductors on ebonite blocks mounted on the hanger bolts.

To use two conductors with three-phase current, the primary current is brought through a special transformer. One phase of the secondary current is grounded and connected to the track which is separately grounded. The conductor bars transmit the other two phases. The Cleveland Tramrail Company in one of its bulletins states that this method of transmitting current to tramrail carriers does not improve operating conditions of a-c tramrail motors. Such motors are fundamentally unsuited for conditions requiring delicate speed control and should not be used for extremely severe service. This reference to a-c motors applies only to tramrail service, where loads are light and lift is short, and not to hoist and crane service in general.

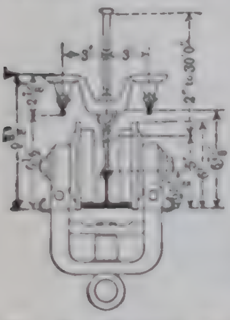

Fig. 13. Tramrail and electric conductor support

TRAMRAIL SYSTEMS. The advantages of tramrail systems are: (1) Little machinery required, cost and maintenance low. (2) No floor space required. (3) Switches permit many tracks to be served by few carriers. (4) Overhead tracks for storage of suspended loads avoid the use of floor space. (5) Standard carriers are available for all kinds of bulk and package material.

Louden Machinery Company, Fairfield, Iowa, makes a standard track of I section, with wide flanges to carry trolley wheels, and for heavier loads a track similar to a 6-in. I beam with strengthened flanges, one flange wide, the other narrow. They are 6 to 16 ft long, carried by hangers spaced to suit the load. Trolley wheels are drop forged, ball bearing, to carry loads up to 5000 lb. Trolleys can be driven by motor or operated by hand.

Richards-Wilcox Company makes an I-beam track (Figs. 8 and 12) for heavy work, and a pressed sheet steel track (Fig. 14) for lighter work, in 10- or 12-ft lengths of No. 10, 13 or 14 gage steel. Trolley wheels for the size shown are 3 in. in diameter, ball or roller bearing, and are assembled in groups of 4 to 16 with equalizer bars to carry loads up to 3000 lb. The track is made with switches, crossovers, turntables, drop sections, hangers, and brackets to suit different conditions.

Figure 15 shows American Monorail track, made by the American Monorail Company, Cleveland, Ohio, in lengths up to 16 ft, and clamped to drop-forged suspenders. The track is made with staggered joints. It assembles 2 in. wide, 2 1/2 in. deep, and will carry loads up to 4000 lb, depending on spacing of hangers and number of trolley wheels. For spans in the open, or where hanger bolts cannot be used, the halves of the rail are welded to the web of a T beam. Trolley wheels are drop forged, 4 in. in diameter, ball bearing, and are assembled in groups of 4- or 8-in. carriers with drop-forged wheel yokes, equalizers, and load bars.

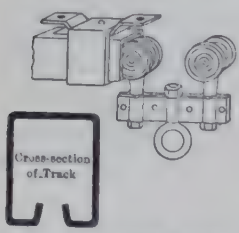

Fig. 14. Pressed steel tramrail track.

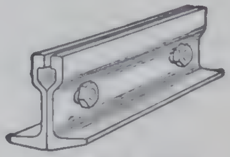

Fig. 15. American Monorail track.

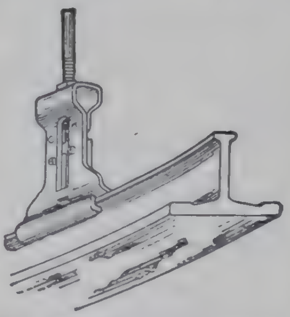

Fig. 16. Cleveland Tramrail track support.

Figure 16 shows Cleveland track. It is about 3 by 3 in., 7 lb per ft. Hanger rods, spaced 3 to 10 ft, support the rail, a clamp on the lower end gripping the rail. A ball-and-socket joint at the upper end permits some free movement, allowing track to adjust itself to load, giving trolley wheels a fair bearing on tread of the rail. On curves, where the load tends to swing outward, the rail is free to tilt slightly, and wheels on the inside of the curve are not overloaded. Trolley wheels are 3, 4, or 5 in. in diameter, ball bearing. Curves, switches, turntables, transfers, and fire-door arrangements have been standardized. This system uses hand- or motor-propelled carriers, with or without hoists, to carry loads of 500 to 4000 lb. Carriers are made for suspended tiering machines and furnace chargers. Foundry ladles for one-man operation have hoist control buttons on the tilting handle of the ladle. Power-propelled carriers with suspension frames for ladles have controllers for tilt, travel, and hoist in the operator's cab or platform. This system also provides automatic dispatch with distance control and special devices for high-speed or continuous travel. With any tramrail system it is possible to arrange track turn-outs to register with various positions of transfer bridges or overhead cranes, enabling carriers to cover a large area.

12. POWER-OPERATED HOISTS

POWER-OPERATED HOISTS. Steam, gasoline and electric hoists for mine, quarries, building erection, logging, and grab-bucket work are available. Single-drum hoists are used for cargo hoisting and building construction, double-drum hoists for general hoisting, and grab-bucket work with straight booms. To operate grab buckets on derricks, three drums generally are used, for the holding line, closing line, and for luffing the boom, respectively. For operation of grab buckets, see p. 26-12. Swing boom derricks require an extra pair of drums to swing the boom. (See p. 26-16.) On small rigs, the bucket-holding line can be wound on a drum, separate from the main hoist, operated by a counterweight rope on the same drum and controlled by a brake. With one of these, a hoist with a single drum for the closing line will work a grab bucket.

Small winches, winding drums, car pullers, and drag scrapers, made to operate by compressed air, are furnished in sizes from 750 to 2000 lb. In the Sullivan Turbinair portable hoist the air motor is located in the hollow of the drum. A 3-hp hoist will wind 350 ft of $^5/_{16}$-in. rope and exert a pull of 1000 lb at 130 ft per min. It weighs 175 lb, and is 20 by 15 by 12 in. overall. The handles control clutch and brake. These machines are made with single or double drums or winch heads. They can be bolted to wood or steel plate bases, or clamped to pipe posts or to the masts of derricks. Air-driven hoists mounted on trailer trucks with gasoline engine, compressors, and air tanks also are available.

Many makers of electric hoists supply winches or pulling machines for bolting to floor or ceiling, or mounted on a truck or skids to form a portable winch. American Engineering Company, Philadelphia, makes single-drum pullers of this type in three sizes. The smallest is 21 by 23 in., 15 in. high, has a 2-hp motor, will wind 250 ft of $^3/_8$-in. rope, and exert a pull of 1000 lb.

CAR PULLERS OR SPOTTERS for moving or spotting freight cars are made by various manufacturers. The car spotter is a compact machine of the vertical capstan type, with gearing enclosed and running in oil. The operator throws a few wraps of rope around the capstan and maintains a hand pull on the slack rope as it pays off.

AIR HOISTS FOR SHOP USE. Direct lift hoists (Fig. 17) have cylinders in diameters up to 19 in. and lengths to suit the work, with lifting capacities up to 10 tons at 80 psi air pressure. They are made single acting for simple rapid lifting, or as balanced-pressure cylinders, in which air acts at full pressure on one side of the piston but is varied on the other by a hand-operated valve. The piston moves under a difference of pressure, and speed and travel are accurately controlled. Air cylinders can be hung from trolleys if the travel is not too great.

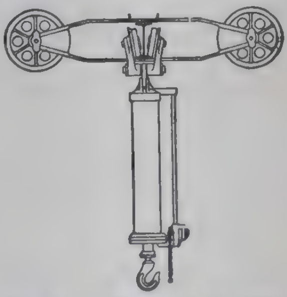

FIG. 17. Direct lift air hoist.

Advantages claimed for direct acting air hoists are: (1) They will work under conditions of dust, moisture, fumes, etc., injurious to other hoists. (2) Few parts to get out of order; repairs can be made by any mechanic. (3) Accuracy of control. (4) Low first and operating cost, including maintenance and depreciation.

GEARED HOISTS operated by compressed air are available. A balanced 2-, 3-, or 4-cylinder engine drives a wire rope drum or chain pocket wheel, through gears enclosed in a tight lubricant-filled case. Sizes range from 500 lb to 10 tons capacity. They weigh two or three times as much as hand-chain hoists but are lighter than the ordinary electric hoists, especially in smaller sizes. They are useful in shops and foundries where compressed air is available and where the hoist can be hung from a fixed point or a trolley with travel not too long for the air hose. They are not easily affected by heat and dust in foundries, and since the valve control is accurate and delicate, patterns, cores, and flasks can be handled with certainty and safety.

GENERAL CONVEYING AND ELEVATING

13. CARRIERS AND ELEVATORS

SKIP HOISTS comprise a single-drum winding machine, a wire rope, a skip or bucket which takes its load below, and dumps it above, together with the necessary lead sheaves, skip filling device, and electrical-control apparatus for the winding machine. Skip hoists are simple in construction and relatively cheap to maintain and operate. Carrying capacities can be made to suit the smallest or largest boiler houses. The path of the skip can be vertical, inclined, or a combination of both. Carrying capacities depend on size of skip, speed of travel, method of loading, whether or not the skip is counterbalanced, and whether operation is full or semi-automatic. Makers' catalogs give tables of expected capacity under various conditions. Skip hoists have been well standardized by manufacturers of conveying and hoisting machinery. Their catalogs give detailed information about track hoppers, loaders, skips, steel structures, winding machines and electrical control apparatus.

Skip hoist with traverse motion is a form of skip hoist, first used to load anthracite or coke to silo bins in retail coal yards. A latched-bottom bucket takes its load of 1 or 2 tons from a track hopper with an automatic feed chute. When hoist is started the bucket rises, comes in contact with a trolley carriage, moves horizontally to a chosen point, then lowers. When bottom of the bucket touches material in the bin, the doors open and contents slide out. The bucket then returns for a new load. Some of these hoists have full-automatic push button control. See Refs. 1 and 2.

PIVOTED BUCKET CARRIERS consist of round-bottom buckets, pivoted between two long-pitch roller chains, arranged to dump on a horizontal run by tipping the bucket. They can be run vertically, horizontally, or in an inclined path. Suitably combined with crusher and feeder, they fit many arrangements of railroad track, boiler house, and storage bin. Where lift, travel, and capacity required are not too great, a pivoted bucket carrier is economical and convenient to install and operate.

Most carriers of this type have overlapping buckets which can be fed continuously from a chute. The chains have hardened pins and bushings, self-oiling rollers, and other refinements. The difference between different makes is chiefly in the suspension of the buckets, and making them lap properly at corner turns. Sizes of buckets, capacities, clearances, power required are practically the same for all such carriers made in the United States. See Tables 1 and 2.

Table 1. Standard Sizes of Pivoted Bucket Carriers

(Courtesy of Link-Belt Co., Philadelphia)

Size of Bucket, in., Length × Width	Pitch of Chain, in.	Carrying Capacity of Bucket, cu ft	Coal Capacity, tons per hour	Speed, ft per min
18 × 15	18	0.68	15– 20	30–40
18 × 21	18	0.94	20– 30	30–40
24 × 18	24	1.68	40– 50	40–50
24 × 24	24	2.24	55– 70	40–50
24 × 30	24	2.80	75–100	40–50
24 × 36	24	3.36	90–120	40–50
30 × 24	30	3.50	95–120	45–60
30 × 30	30	4.37	110–160	45–60
30 × 36	30	5.25	140–190	45–60
36 × 36	36	8.50	210–330	50–80

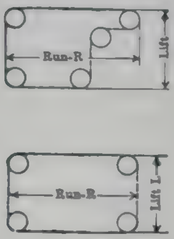
The horsepower required at the head shaft of a pivoted bucket carrier is

$$\text{Horsepower} = AL + BR \tag{1}$$

where L = total vertical lift, feet, R = total horizontal run, feet (see cut in Table 2), A and B are factors whose values are given in Table 2. Add 10% for each cast gear drive, and 5% for each drive through belt, chain, or cut gears.

Pivoted bucket carriers are quiet in operation, convey and elevate at the same time and thus avoid transfers and deep pits. They require little power. They cannot be fed on a vertical run nor under a turn wheel. The dump must always be on a horizontal run. Catalogs of manufacturers give dimensions of drive groups, corner turns, and clearances.

Table 2. Horsepower Factors of Pivoted Bucket Carriers
(Courtesy of Jeffrey Manufacturing Co., Columbus, Ohio)



Size of Bucket		Loaded on One Vertical and Both Horizontal Runs — Power Factors			
		Material 50 lb per cu ft		Material 100 lb per cu ft

30	30	.198	.061	.396	.085
30	36	.238	.070	.476	.100

CENTRIFUGAL DISCHARGE ELEVATORS. The simplest form of elevator consists of malleable-iron buckets fastened at intervals to a single chain. It is called a "centrifugal discharge" machine because the contents of the buckets are thrown out at the head wheel by centrifugal force. A full, clean discharge into the head chute depends chiefly on the size of the head wheel, its speed, and the bucket spacing. Table 3 gives the result of practical experience with vertical centrifugal discharge coal elevators. Belts with buckets attached are used for fine, dry, or gritty materials, but chain is better for the rough work of elevating coal. Figure 1 shows style A malleable-iron buckets, used in coal elevators. The buckets will not discharge clean if set too closely together. For analysis of conditions of pick-up and discharge of centrifugal bucket elevators, see Ref. 3.

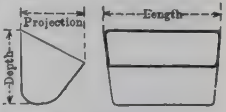

FIG. 1. Malleable-iron elevator bucket.

Table 4 gives the closest possible spacing for the speeds given in Table 3. If spacing does not match pitch of chain, increase it to a multiple of that pitch. If the coal is lumpy, increase the spacing. To determine the size of chain, working strengths alone, as given in makers' catalogs, are not a suitable guide. A link should be chosen which bears a proper proportion to the dimensions of the bucket, and which has a bucket attachment large enough for the bucket. K1 attachments have two bolt holes; K2 attachments have four bolt holes and are advisable for buckets 8 by 5 in. and larger. The greater the projection of the bucket, the greater should be the pitch of the link to give the bucket a proper support in picking up its load. Table 5 represents good practice.

Table 3. Speeds for Vertical Centrifugal-discharge Coal Elevators

Diameter, head wheel, inches	18	21	24	27	30	36	42
Revolutions per minute	46	43	41	39	37	34	32
Speed of chain, feet per minute	217	237	257	276	290	320	352

Note. Permissible variation not over a few rpm either way.

Table 4. Minimum Spacing Style A Buckets for Clean Discharge

Projection of bucket, inches	4	5	6	7	8
Closest spacing, inches	10	12	14	17	20

Table 5. Pitch of Chain for Style A Malleable-iron Buckets

Size of bucket, in., length × projection	6 × 4	7 × 4 1/2	8 × 5	10 × 6	12 × 7	14 × 8	16 × 8
Pitch of malleable-iron chain, in.	2.6	2.6	3.1	3.1	4.7	6	6

Table 6 gives weights and capacities of buckets used in simple coal elevators. The diameter of the foot wheel of a centrifugal discharge coal elevator should be at least four

Table 6. Weights and Capacities, Style A, Malleable-iron Buckets

Size of bucket, in., length × projection	6 × 4	7 × 4 1/2	8 × 5	10 × 6	12 × 7	14 × 8	16 × 8
Weight, lb	2.2	3	4	6.4	9.6	13.2	21
Coal capacity, lb (*C* in formulas)	1.5	2.2	3	5.2	8.3	13.9	18.9

times the pitch of chain used. If the wheel is too small, buckets will not fill properly. The following formulas are applicable to bucket elevators:

Notation. C = pounds of coal per bucket (see Table 6); D = diameter of foot wheel, inches, hp = horsepower to be delivered to the elevators; L = height of lift, feet; P = pull in chain, pounds, due to pick-up of coal at foot of elevator; S = spacing of buckets, inches, T = travel of chain, feet per minute; U = unbalanced pull in chain due to weight of coal in buckets; W = capacity of elevator, pounds of coal per minute; X = theoretical horsepower required.

$$P = \frac{12DC}{S} \tag{2}$$

$$U = \frac{12LC}{S} \tag{3}$$

Combining eqs. 2 and 3 gives

$$X = 12\frac{C}{S}(L + D)\frac{T}{33{,}000} \tag{4}$$

Allowing 30% for losses in power transmission,

$$\text{Hp} = 0.0005\frac{CT}{S}(L + D) \tag{5}$$

$$W = \frac{12CT}{S} \tag{6}$$

The head chute of a centrifugal discharge coal elevator should have a slope of at least 35 degrees, and its upper end should not be above a line drawn at 45 degrees through the center of the head wheel.

The lower wheel of a centrifugal discharge coal elevator generally is enclosed in a cast-iron or steel plate box, called a boot, which serves as a support for shaft bearings and also confines material to the path of the buckets. Boots with fixed bearings generally are not used for coal elevators, those with adjustable bearings being convenient. For sizes and dimensions, see makers' catalogs.

Advantages and Limitations. The centrifugal discharge elevator is cheap and simple, takes up little space, does not require deep or large pits, and can be encased easily. It will give good service when worked for a few hours each day, but for lumpy material, large capacities, and long hours of service, it is better to use a heavier machine at slower speed. Such machines comprise continuous bucket elevators, perfect-discharge elevators, and V-bucket elevators.

CONTINUOUS BUCKET ELEVATORS consist of single or double chains with an endless series of steel buckets so shaped that in passing over the head wheel each bucket acts as a deflector or chute for the discharge of the contents of the following bucket. Single-strand machines use K2 attachments fastened to the backs of the buckets, the depth of the bucket being 2, or rarely 3, pitches of the chain. Angles usually are fastened to the bucket ends to guide the vertical runs. Long buckets for large capacities require two chains, fastened to the ends. The chains usually are of steel, with a pitch equal to the depth of the bucket. In this position the chains guide the vertical runs. For inclined runs, they can be fitted with rollers that run up and down on suitable tracks. Buckets for vertical elevators handling crushed coal (Fig. 2) are made with the angle B in the bottom equal to 55 degrees, thus giving a chute or discharge angle of 35 degrees, which is steep enough for crushed coal. If the coal is all fine or wet, B should be 45 degrees; angle A then is 45 degrees, giving a better delivery into the head chute. When the elevator is inclined 25 or 30 degrees from the vertical, as in Fig. 3, B can be increased to 70 degrees to give more bucket capacity, and for ordinary crushed coal the discharge will be clean. This is one advantage of inclining such an elevator; another is that material can be delivered directly to the buckets by a chute without spill. These buckets will pick up soft material like crushed coal from a boot, but not hard lumpy material like stone. Stone and ores should be handled in inclined elevators, with the feed directly from a chute set 2 or 3 buckets above the foot wheel, and the foot of the elevator must be free and open to allow spilled material to fall clear of the buckets and be shoveled up. The head chute never

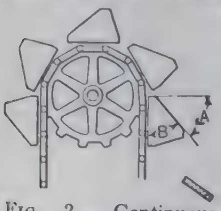

FIG. 2. Continuous bucket elevator.

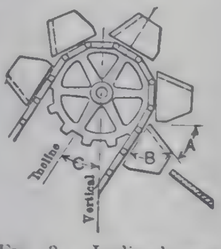

FIG. 3. Inclined continuous bucket elevator.

must be above a line drawn at 45 degrees through the center of the head wheel. Speeds range from 90 to 200 ft per min in handling coal.

For horsepower required by continuous bucket elevators, use eq. 5; for capacities, use eq. 6; for diameter of head shaft, see p. 26-35.

The continuous-bucket elevator is especially adapted for handling stone, but in elevating crushed coal for boiler houses it has the merit of giving high capacities at speeds much lower than those of centrifugal discharge elevators. For handling run-of-mine or large lump coal, the V-bucket elevator is generally better.

PERFECT-DISCHARGE ELEVATORS have two strands of chain fastened to the ends of the buckets. The buckets are not continuous, and the speed is slow as compared with centrifugal discharge elevators. In order to effect a clean discharge, the chains are deflected backward under the head wheels by a pair of supplementary wheels in such a way that the contents of each bucket will fall clear of the bucket ahead. Figure 4 shows the location of the deflector wheels with reference to the head wheels. Table 7 is based on good practice and gives dimensions for elevators using malleable-iron style A buckets and with wheels arranged according to Fig. 4. These elevators often are built with sheet steel buckets for larger capacities of coal, at speeds between 100 and 150 ft per min.

Table 7. Data for Perfect-discharge Elevators, Style A Buckets

Projection of bucket, in.	5	6	7	8	9	10

Measure *A* down from center of head wheel. Draw line 50 degrees from vertical. Measure *B* from intersection to center of deflector.

For horsepower, use eq. 5; for capacities, use eq. 6; for diameter of head shaft, see p. 26-35.

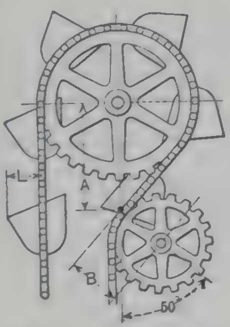

Fig. 4. Perfect-discharge elevator.

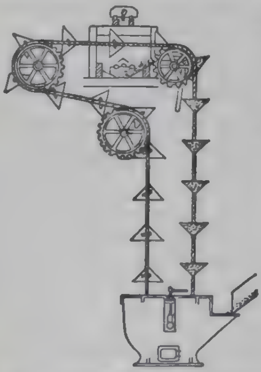

Fig. 5. V-bucket carrier.

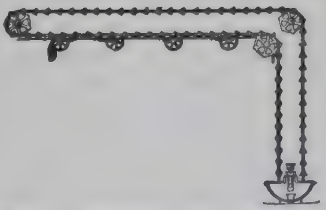

Fig. 6. V-bucket carrier with boot.

Advantages of the Perfect-discharge Elevator. (1) It has two chains, and as usually designed, has a large margin of safety between the working strain and the breaking strength of the chains. (2) The pick-up of material is easy. (3) On account of the slow speed, the chains, buckets, wheels, gears, and bearings last longer and require less attention and repair. As an offset, the machine costs more than a single-strand elevator.

THE V-BUCKET CARRIER GRAVITY DISCHARGE MACHINE is used extensively for handling coal, either lump or crushed. It consists of two roller chains fastened to the ends of V-shaped buckets which carry the coal on vertical or inclined runs and push it along a trough on the horizontal run. Gates in the trough permit the coal to be discharged where it is wanted. When arranged as in Fig. 5 or Fig. 6, it will pick up from a boot; with the path shown in Fig. 7, it will pick up at any point on the bottom run as well as at the corner turn.

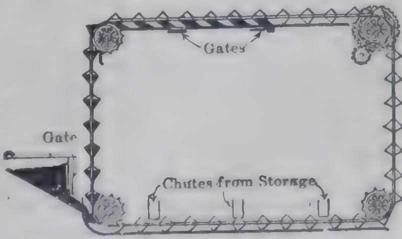

Fig. 7. V-bucket carrier in boiler house.

The 12-in. and 16-in. buckets sometimes are carried on malleable-iron roller chains, but steel bar chains generally are used for the larger sizes, and are better for the small sizes also. Take-ups or adjustable bearings always should be placed at a corner where the buckets pass empty, not at a corner around which coal travels. Vertical runs always should be encased to confine the spill and to avoid exposure to rain and snow.

Advantages of V-bucket Carrier. (1) Strong and rugged; will carry any coal up to run-of-mine size, at speeds up to 120 ft per min. (2) Will receive on any run or from a boot. (3) Handles coal without breaking it. (4) Gives larger capacities than pivoted bucket carriers.

Disadvantages. (1) Requires more power on horizontal runs than other types. (2) Not suitable for ashes or hard and gritty material. (3) As compared with other elevators, it cannot discharge over a head wheel, but always must discharge on a run between two sets of wheels.

HORIZONTAL DISTRIBUTION BY BELT OR FLIGHT CONVEYOR. Inclined conveyors sometimes are used for elevating coal when the boiler house is at a distance from the track. If the house is not too long, the inclined conveyor may be carried over a hump into the horizontal, but if the house is long, or if its axis is not in line with the conveyor from the track, a separate conveyor must be used for distribution in the house. A similar condition exists in boiler houses where the ash disposal is by car or hoist. In such cases, where a pivoted-bucket or a V-bucket carrier cannot well be used for distributing, a simple coal elevator or a hoist is used for lifting the coal.

Whether to use a belt conveyor or a flight conveyor depends partly on the structures and operating conditions, and partly on the personal preferences of engineers and owners. Considering only physical conditions, belt conveyors may be regarded as best (1) where the bin is long, say, 150 ft or more; (2) where the capacity is more than 100 tons an hour; (3) where noiseless operation is essential.

A flight conveyor may be best (1) where there is no room to admit a belt tripper; (2) where the first discharge is less than 20 ft from loading point of the conveyor, a distance too short to admit a tripper; (3) when the conveyor is shorter than 50 ft center to center; (4) where separate spaced bins are used, instead of one continuous bin; (5) where the conveyor is exposed to rain, snow, or freezing.

For either machine, these limits are not hard and fast, and between them there are chances to exercise personal preference or judgment. Both machines have been on the market for many years and have been standardized. There is no "universal" conveyor; for handling heavy or gritty ores, as in the Western smelters, or in conveying heavy tonnages of coal over long distances, as in by-product coke plants, a flight conveyor is not to be considered; but in many boiler houses it makes the best distributor, even though it requires more power. The older forms of flight conveyor were noisy, but modern roller-flight conveyors, or double-strand roller-chain conveyors, are by comparison almost noiseless. They are strong and rugged, easy to load and discharge, and will work under conditions and lack of care that would be harmful to belts. Some engineers have a prejudice against scraping the coal in a trough. It does consume more power, but it does not harm even anthracite. As to wear on the trough, the item of replacement is not an important one.

CHAIN PULLS AND HORSEPOWERS. The general formula for any ordinary flight conveyor, apron conveyor, bucket elevator, or bucket carrier is

$$\text{Pull} = P = X + Y + Z \tag{7}$$

where X = pull to move the weight of material, coal, etc., on the loaded run; Y = pull to move the conveyor parts on the loaded run; Z = pull to move the conveyor parts on the empty run.

$$X = WL(F\cos\alpha + \sin\alpha);\ Y = W_1L(f\cos\alpha + \sin\alpha);\ Z = W_1L(f\cos\alpha - \sin\alpha),$$

where W = weight of coal, etc., pounds per foot; W_1 = weight of conveyor parts, pounds per foot; L = length of conveyor, feet; α = angle of inclination from the horizontal; F = coefficient of friction for the material (coal, etc.); f = coefficient of friction of moving conveyor parts.

For anthracite, $F = 0.33$; for bituminous coal, $F = 0.50$. For conveyor parts, sliding in a trough or on tracks, $f = 0.33$; for conveyor parts, rolling on tracks, $f = Nd \div D$, where D = diameter of chain roller, inches; d = size of hole in roller, inches; N = factor determined by the kind of hole and the grade of lubrication. For a smooth hole, not lubricated, $N = 0.5$; for a smooth hole, greased, $N = 0.33$; for a bored hole, greased, $N = 0.25$; for a bored hole, well oiled, $N = 0.20$. For vertical lifts, $\cos\alpha = 0$; for horizontal runs, $\sin\alpha = 0$. For ordinary bucket carriers, apron conveyors, etc., where the material is carried, and not scraped, $F = f$.

If material is carried down hill or lowered, sin α becomes negative and then

$$X = WL(F \cos \alpha - \sin \alpha);\ Y = W_1L(f \cos \alpha - \sin \alpha);\ Z = W_1L(f \cos \alpha + \sin \alpha).$$

For combined elevator conveyors of complicated path, make a diagram of the path, calculate the pull for each run separately, note it on the diagram with a plus sign if positive and with a minus sign if the pull is in the direction of motion of the machine. Add the several values, allowing at each turn, where pull is transmitted, 5% of the accumulated pull up to that point. Note P, the maximum pull where the chain enters the driving sprocket wheel, and P_1, the pull on the chain leaving the wheel. Then P determines the stress in the chain, and $(P - P_1)$ is the torsional pull on the driving wheel. From this

$$\text{Hp} = \frac{T(P - P_1)}{33{,}000} \tag{8}$$

where T = chain speed, feet per minute. For the size of the motor, increase horsepower by 10% for each pair of cast-tooth gears, and by 5% for each drive through belt, chain, or cut gears.

SIZES OF SHAFTING FOR ELEVATORS AND CONVEYORS OF ALL KINDS. Head shafts and important turn shafts should be calculated for torsion and bending. From eq. 8, $(P - P_1)$ is the torsional pull; this multiplied by the radius of the sprocket wheel gives the torsional moment in inch-pounds. The load which produces bending is the resultant of two forces. One of these is $(P - P_1)$; the other is the weight of the shaft, wheels, and gear. In a vertical machine, the resultant is the algebraic sum of the forces. For other machines the weight of shaft, etc., is ignored, if it is proportionately small; otherwise the resultant is found by means of a diagram of forces. The shaft then may be considered as a beam supported by its bearings, and the bending moment in inch-pounds determined. By observing where the bending stress and the torsion stress act together on the same cross section of the shaft, the shaft diameter may be obtained from Article 2, Section 15.

CHAINS FOR FLIGHT CONVEYORS. Malleable-iron hook-joint chains are used for simple flight conveyors without rollers when the pull is not over 1500 lb. For roller flights, malleable-iron, closed-joint chains, or chains of the steel bar type are common. For double-strand conveyors with flights 20 by 10 in. or smaller, and of moderate length, malleable-iron roller chains are used; for larger flights and for heavy duty, steel bar chains are better. They are made in pitches 9 to 24 in. and of a strength to meet any service.

HANDLING ASHES IN BOILER HOUSES. For pneumatic system, see p. 26-43; for hydraulic methods, see p. 26-45; for skip hoists, see p. 26-30; for pivoted bucket carriers, see p. 26-30.

In small plants, ashes often are collected by hand car and taken to a waste dump, or discharged into a skip or elevator for storage in a bin. Ashes elevators which work only an hour or two per day are of the centrifugal discharge type (see p. 26-31) with a chain strong enough to withstand grit and corrosion. If the machine must work longer, it is better to use a slower speed elevator or a skip hoist. For handling large clinkers, old brick, soot, and other boiler house refuse, a car and skip system is better than any bucket elevator. For high lifts a skip hoist is better under any conditions.

A simple ashes conveyor used in some small boiler houses consists of a wide malleable-iron chain which runs at about 5 ft per min in a heavy cast-iron trough and partly drags, partly carries the ashes to the foot of an elevator. It is cheap, requires no lubrication, and lasts long enough to pay for itself in some places.

14. ELEVATORS FOR MATERIALS OTHER THAN COAL

It is necessary to consider whether material to be handled is fine or in large pieces, abrasive or nonabrasive, friable or nonfriable, wet or dry, whether or not it must be handled at slow speed. It is not possible to give exact rules, but for most cases the following directions are useful.

(1) Ashes, crushed ores, small coal, foundry sand, dry clay, gypsum, acid phosphate, and similar materials. Use centrifugal discharge elevators with malleable-iron buckets on single-strand closed-joint, or steel-bushed malleable-iron, chain.

(2) Grains, feeds, and other free-flowing materials. Use centrifugal discharge elevators with chains lighter than those in (1) or rubber belts, with malleable-iron or sheet-steel buckets.

(3) Cement, crushed coal, coke, slag, ores, glass house cullet, and other material, not too large, which should be handled at relatively slow speeds. Use single-strand continuous-

bucket elevators with steel buckets on closed-joint or steel-bushed malleable-iron chains. These elevators are vertical, or nearly so, and have a boot and casing.

(4) For materials in (3), handled in large quantities or to high lifts, use double-strand continuous-bucket elevators with steel buckets on steel chains.

(5) Heavy coarse material, ores, crushed stone, gravel, and rock which cannot be picked up in a boot. Use inclined continuous-bucket elevators with one or two strands of chain or a rubber belt.

Elevators for handling coal in boiler houses and for many other materials have been classified and standardized by manufacturers of conveying machinery, whose catalogs give dimensions, capacities, speeds, power required, and details of casings, boots, etc. For belt elevators, see handbooks issued by rubber belt makers: Goodyear Rubber Company, Akron, O., Goodrich Rubber Company, Akron, O.; Manhattan Rubber Company, Passaic, N. J., and others.

PORTABLE ELEVATORS OR LOADERS are bucket elevators with a motor or gasoline engine mounted on wheels or caterpillar treads, and arranged to pick up their load at ground level and deliver it to wagons or trucks through a chute, screen, or short belt conveyor. Some loaders for hard coal, coke, or excavated gravel have shaking screens. In coal yards, they save time and labor and reduce cost of handling by keeping trucks at work. A man will shovel a ton of coal from ground to wagon in 20 min; a loader in 3 min or less. Four men load a 5-ton truck by hand in 30 min; one man with a loader in 5 min. The system of using loaders in connection with ground storage is preferred by many to storage in overhead bins with chutes to wagons. First cost and depreciation are less and there is less machinery to maintain. For large capacities, or where a machine handles sand, stone, or gravel, a self-propelled machine (Fig. 8) is an advantage. The loader backs into the pile by its own power, which is quicker and easier than breaking down the pile by hand. Loaders that work on roads or in yards with soft floors should have track-laying treads.

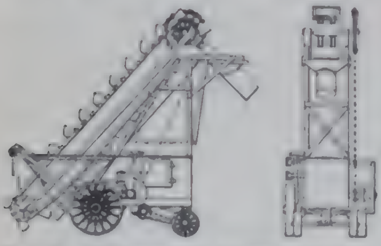

FIG. 8. Self-propelled loading machine.

Portable elevators, in modified form, excavate earth, dig trenches for pipe lines, remove snow from city streets. A development by Barber-Breene is a portable road-building machine that travels under its own power, picks up sand and gravel, mixes it with bituminous binder, spreads, tamps, and levels it to make a finished road at the rate of 1 mile per hour.

VIBRATING CONVEYORS, mounted on roller races for use in mines, are described below. Similar conveyors with the trough mounted on spring legs are used for sugar and other materials not easily handled by screw, flight, or apron conveyors.

Vibrating pipe conveyors made by Traylor Vibrator Company, Denver, Colo., are used to convey roasted ores, sintered concentrates, and other hot, dusty, and gritty materials. The pipes are 10 to 26 in. in diameter, hung by flexible suspension from above. Vibrating units are clamped to the pipe at intervals, each consisting of an armature and a stator supplied with alternating current. At 60 cycles per second the armature is attracted 3600 times per minute against the flexure of powerful bar springs. The inertia of heavy weights attached to the frame causes the pipe and armature to vibrate in unison. The plane of vibration is inclined to the axis of the pipe, and the material receives a component of motion, which moves it through the pipe. See Ref. 4.

The Redler conveyor (Stephens-Adamson Manufacturing Company) consists of a flexible chain or wire rope carrying pusher bars or links at short intervals. These move in a closed box, embedded in the material conveyed. By a proper arrangement of turns, horizontal and vertical runs can be combined, and the machine acts both as elevator and conveyor. Moving parts do not completely fill the cross section of the box, and the conveyor is said to be free from danger of overloading.

15. COAL CONVEYING IN THE MINE

COAL CONVEYING BY MINE CAR HAULAGE. Robert Peele (Ref. 5) says that locomotive haulage is justified at mines with easy track grades and large output. Compared with haulage by animals, the high speed, large tonnage per trip, and few men required may balance the larger interest and depreciation charges. Compared with rope haulage, especially if there are branches or many curves, it is more flexible and easier to extend or maintain. It requires less headroom, heavier rails, and easier curves than animal haulage, but cannot compete with it on thick seams in daily output of less than about 175 net ton-miles on grades below 1.25%, or with rope haulage on grades averaging 4% against or 5% with loads.

Gasoline locomotives have the flexibility of steam locomotives in radius of travel, and for mining work are geared for speeds of 3 to 12 miles per hour. They have no open fire, consume no fuel when idle, and are less dangerous than steam locomotives in gaseous mines. Exhaust gases and cost of gasoline are factors to consider.

Compressed-air locomotives are flexible in operation within the radius of travel from charging stations for which they are designed, require no fire, do not spark or emit noxious exhaust, but aid ventilation and are the safest type for gaseous, dry-timbered or poorly ventilated workings.

Electric storage-battery locomotives are flexible, cheaper to install than trolley or air locomotives, simple to operate, and safer than any other type except compressed air. They are suitable for short hauls, in temporary workings, as in gathering, or for infrequent long hauls where trolley lines are not warranted or where low-roofed wet workings make them dangerous. Grades must be easy.

Electric trolley locomotives are the prevalent types in mines. They are compact, simple to operate at high efficiency, and usually have lowest power cost of all types. Disadvantages are cost and danger of trolley circuit; danger of sparking at commutator or trolley wheel; necessity of wired and bonded track.

Rope haulage conditions are large tonnage and grades which make locomotive haulage inefficient. Straight haulways and uniform grades are desirable but not necessary. See Rope Haulage, p. 26-09.

UNDERGROUND CONVEYING BY BELT CONVEYOR. A belt conveyor system may handle large quantities of materials in mines at a lower cost than any system of haulage. At the Colonial mines of H. C. Frick Coke Company, near Brownsville, Pa., trains of cars in the mine are turned over in a rotary dumper; the coal falls into a bin and is fed by feeders to a 60-in. belt which delivers to a series of nineteen 48-in. belts run at 500 ft per min, and of lengths of 321 to 2439 ft. The total run is 4 1/2 miles; the total lift is 357 ft.

The system was planned and installed after the estimate had shown a probable saving of 3 cents per ton, 10,000 tons a day, based on the following comparisons between the belt system and haulage by electric locomotive. (1) First cost, belts 25% less. (2) Depreciation, belts 15% more. (3) Cost of power, belts 100% more. (4) Cost of labor, belts, 50% less. After eight years in service, the system had carried over 25,000,000 tons of coal, and eight of the original belts were still in use. Records and tests have shown the cost of power for the belt system to be less than half of that estimated, the saving in labor to be greater than estimated, and saving in cost of conveying to be over 3 cents per ton. For a description of this system, see Ref. 6 and Ref. 3, pp. 273–274. A belt conveyor similar to the above is used at the Palmer mines of H. C. Frick Coke Company. It has twelve belts with a total length of travel of over 3 miles.

RETARDING CONVEYORS. In parts of West Virginia and Kentucky, coal veins are on the hills and railroad tracks in the valley. An old way to get coal down is in coupled mine cars lowered down the slope by a tail rope. A broken car coupling or rope may cause a runaway resulting in great damage or loss of life. Coal sometimes is lowered in a large skip (monitor or gunboat), but unless it is shipped as run-of-mine, breakage due to filling and emptying the skip is objectionable. Wire-rope tramways have been used for capacities of a few hundred tons per day (see p. 26-09). For larger capacities, retarding conveyors are used.

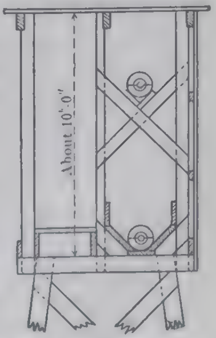

FIG. 9. Wire-rope retarder.

The wire-rope retarder, Fig. 9 (Jeffrey Manufacturing Company, Columbus, Ohio) comprises an endless wire rope to which 12 in. diameter cast-iron disks are clamped at intervals of 3 or 4 ft. On the carrying (lower) run the disks travel in a V-shaped trough with rounded bottom. On the return they run in a small guide trough. The rope, 7/8 to 1 1/8 in., generally is made with six flattened strands (see p. 6-14) arranged alternately, regular lay and lang lay so that the rope does not twist or rotate. The ends are joined in a split clamp disk. Rope retarders can be used on any slope up to 35 degrees and up to 1000 ft long. The best slope for soft coal is about 26 degrees. For slopes over 30 degrees, hinged baffle boards over the trough stop lumps if they start to avalanche. A straight run is preferable, but if slope must change from steep to flat, a large radius curve (1000 ft) should be made in the trough, or one conveyor must be made to discharge into another. As the wire rope is submerged in coal, wheels or tracks cannot be used to hold the rope down. At terminals, the rope runs over toothed wheels. On all but flat slopes, brakes prevent the conveyor drifting when power is off. On steep slopes a hand-operated brake also is used. Rope retarders have been used for 50 years or more. When properly designed and built, they are good and relatively inexpensive. Carrying capacity is 100 tons to 200 tons per hour.

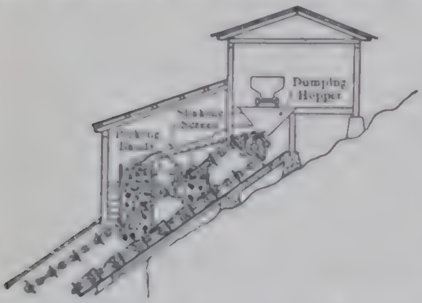

Fig. 10. Retarding conveyor loading end.

Chain and flight-retarding conveyors consist of two strands of steel roller chain attached to ends of steel flights, running in a steel trough. The chains roll on tracks, and the path of the conveyor can be made to suit the slope and contour of the ground. A 36 by 12 in. flight will carry 360 tons per hour at 100 ft per min. Some retarders have 48 by 12 in. or 60 by 16 in. flights for large carrying capacity. Figure 10 shows the upper end of a retarding conveyor where a shaking screen separates the fines before the coal goes to the picking bands. With such an arrangement, refuse is thrown out on the slope of the hill.

16. BELT CONVEYORS

For fundamentals of design and operation, see Ref. 3. In its simplest form a belt conveyor comprises two end pulleys, a moving belt, and idlers to support the belt. The lower idlers have flat-faced rolls; the upper or carrying idlers generally are arranged to curve or trough the belt to make it carry more and avoid risk of spill. There is not much difference between 3- and 5-roll troughing idlers in carrying capacity. Three-roll idlers cost less, have fewer bearings, lubrication is more certain. The best troughing idlers have ball or roller bearings; the saving of power, reduced cost of maintenance, and longer life of belt often pay for the extra cost of the improved idlers. On grain conveyor belts, the best practice is to run the belt nearly flat with concentrator or "tuck-up" idlers at intervals to give a slight troughing.

Troughing idlers are spaced 4 to $5\,^1/_2$ ft apart on narrow belts, according to weight of material carried; on wide belts, 3 to 4 ft apart. Return idlers are spaced 9 or 10 ft apart.

For detailed information about belt idlers and other parts, see catalogs of the Link-Belt Company, Chicago; Robins Conveying Belt Company, New York; Stephens-Adamson Manufacturing Company, Aurora, Ill., and other manufacturers of conveying machinery.

THE CONVEYOR BELT may be of solid woven fabric, or of cotton duck with the plies stitched together. Both kinds are impregnated with oils or compounds to resist moisture. Rubber belts, however, are in more general use. They are built up with layers of cotton duck cemented together by rubber compounds, and then vulcanized. Lengthwise threads of the cotton duck are heavier than crosswise to give tensile strength with flexibility for troughing. An extra thickness or cover of rubber on carrying side of the belt resists abrasion and increases its life. For crushed coal, the cover may be $^1/_{16}$ in. thick, but for run-of-mine coal and abrasive ores a thicker cover is required to avoid puncture by sharp pieces, and to resist wear occasioned by making material at the loading point acquire the belt velocity.

BELT THICKNESS. In general, for durability and long life, tension in a rubber or cotton belt should not exceed 24 lb per in. of width per ply of thickness, if duck is the usual 28-oz duck. In a belt conveyor, this 24 lb cannot all be used to move the loaded belt. Some of it must be used to supply enough tension to prevent slip on the drive pulley. This tension is applied by the take-up. The smaller the arc of wrap on the drive pulley and the lower the coefficient of friction between belt and pulley, the greater must be the tension. By increasing angle of wrap and lagging drive pulley, more of the strength of the belt can be usefully employed.

Rubber belts are made in different grades, differing as to weight of duck, quality of "friction" used to cement plies together, and thickness and quality of rubber covers. For detailed information, see Ref. 3, pp. 52ff. Reference 7 gives considerable detailed information concerning belts, tandem drives, stresses in inclined conveyors, etc. See also Ref. 8.

DIAMETER OF BELT PULLEYS. The larger the pulley, the less the stretching of the rubber "friction," or of the stitching which holds the plies of the belt together, and the longer the belt will last. The diameter of driving pulleys in inches should be at least five times the number of plies in the belt. The diameter of foot pulleys and snub pulleys should be four times the number of plies, and of tandem pulleys, geared together, driving thick belts with heavy rubber covers, at least six times the number of plies.

LOADING BELTS. To reduce the wear on the belt surface, the material should be fed by a chute of such length and slope as will give to the material the velocity of the belt, if possible. To prevent scatter, and to pile the load properly, skirt boards 5 to 7 ft long are used. They must be carefully designed. If not well supported, they may sag and cut the belt.

DISCHARGE FROM BELT CONVEYORS. The simplest belt conveyor discharges over the head pulley, as in Fig. 11. For intermediate discharge at one or more points, fixed trippers may be used, as in Fig. 12, but they double or triple the wear on the belt surface whenever they feed material back on the belt, and by repeated reverse bending over pulleys they tend to separate the plies of the belt. For most conditions of intermediate discharge, a traveling or movable tripper (Fig. 13) is preferable. Some materials, like foundry sand or wood chips, can be carried on flat belts, and at slow speeds the discharge can be divided at several intermediate points by "strike-off" boards set at various positions above the belt, or all can be thrown off at any point if the boards are hinged so as to swing into and out of position. This method is not good with lumpy material.

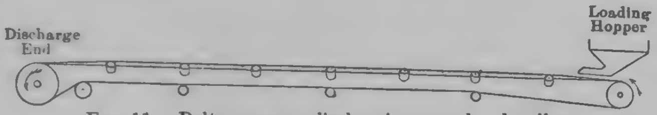

Fig. 11. Belt conveyor discharging over head pulley.

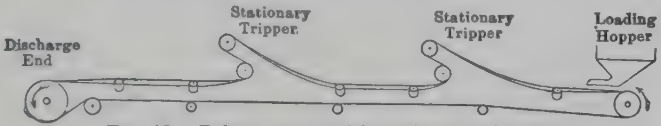

Fig. 12. Belt conveyor with stationary trippers.

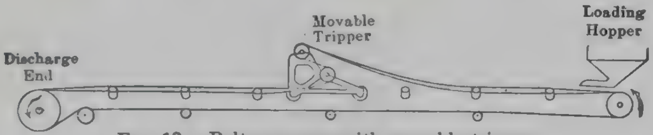

Fig. 13. Belt conveyor with movable trippers.

INCLINED BELTS. With uniform feed, fine coal may be carried on a belt at an angle from the horizontal of 22 degrees; but when mixed with lumps, at an angle of not over 20 degrees. Run-of-mine coal, coal, and coke can be carried at an angle of not over 18 degrees, crushed stone and ore, at not over 18 degrees, and tempered foundry sand at not over 24 degrees. On the other hand, numerous substances under certain conditions can be carried at not over 15 degrees.

ADVANTAGES OF BELT CONVEYOR. (1) Low power consumption. (2) Noiseless operation. (3) Adaptable to all sorts of material. (4) Suitable for high capacities and long distances beyond the range of other conveyors. (5) Simplicity of construction.

LIMITATIONS. The belt is expensive and must be protected from these sources of injury: (1) poor arrangement of feed; (2) chute or skirt-board sagging on belt; (3) lumps falling on return belt and jamming between foot pulley and belt; (4) belt running crooked and fraying the edges; (5) oil or grease getting on rubber belt; and (6) continued exposure to great heat or cold, or direct sunlight.

When belts are inclined, especially at or near the maximum angle, there is a shift or slip of material in passing over each troughing idler. This adds to the wear on the carrying surface, and with gritty materials it may be serious. Short belts, steeply inclined, are likely to be short lived under such conditions, because the wear from the pick-up at the loading point is already large, due to the fact that each foot of belt passes the loading point frequently. In long belts the wear from pick-up is distributed over a greater amount of belt surface, and the bending over pulleys does not occur so often. Hence long belts last proportionately longer than short belts.

STANDARD BELT CONVEYORS, 16 to 48 in. wide for various lengths and capacities, are shown in catalogs of manufacturers of conveying machinery. For many conditions of ordinary service, time and expense can be saved by buying a conveyor from a catalog rather than designing one.

Sectional belt conveyors 18 and 24 in. wide (Barber-Greene Company) consist of standard drive and take-up groups with machinery parts mounted on steel frames. Conveyor length is made up of light steel frames of various standard lengths, which, with belts, idlers, and guards, weigh not more than 60 lb per ft. They will span 25 to 50 ft in the clear.

Portable conveyors of the same light construction, listed by the same makers, are used to receive concrete from mixers and deliver it to forms in building construction. By having one conveyor discharge to the next, concrete can be distributed over large areas. In some cases, 15 conveyors have been used for a distance of 500 ft or more. The 24-in. belt runs over 2-roll idlers to form a deep trough. A flexible scraper under each head pulley removes concrete from the belt. Frames are made up to 50 ft long and are mounted on large caster wheels. For handling concrete on belt conveyors, see Ref. 9.

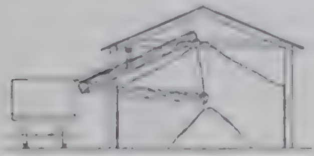

Fig. 14. Portable conveyor for car unloading.

Other portable belt conveyors are made. Figure 14 shows one which stores in a shed, material shoveled over side of a car. The frame is hung from a chain block and trolley on an overhead track that runs the length of the shed. Motor- or gasoline-driven portable conveyors on wheeled frames with 12-, 14- or 16-in. belts on frames 20 to 40 ft long, will receive material from bottom-dump or side-dump cars and form storage piles or deliver to bins or wagons. Several machines can be placed in tandem to deliver to a distance, or a high pile can be formed by arranging machines as in Fig. 15. These machines are light, a 16 in. by 30 ft size weighing less than a ton. Heavy machines of this type are made by Barber-Greene Company, with 18- or 24-in. belts on frames up to 60 ft long, with a hand-power hoist for adjusting height of boom.

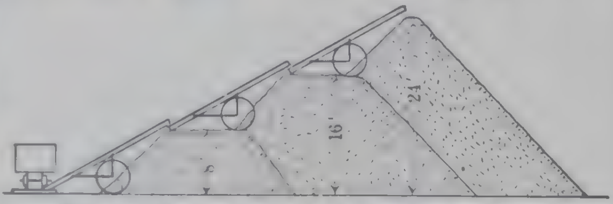

Fig. 15. Portable conveyors arranged for high piling.

CAR LOADER BELTS. Short belt conveyors mounted on wheeled frames easily handled by one man, and run at 1200 ft per min or more, will throw fine material a distance of 15 to 20 ft. The machine is placed in position at door of a box car, receives material from a chute, throws it into a pile at each end of the car, and distributes it for proper loading. It saves the labor of several men.

CAR UNLOADER BELTS (Barber-Greene) are mounted on a shallow steel frame, 4 or 5 in. deep, that can be laid across a track above the rails, or in a shallow pit below them, to receive discharge from a drop-bottom car. They are used for free-flowing materials without lumps. The service is severe, but the car can be unloaded anywhere on the track and a deep pit is unnecessary.

WEIGHING ON BELT CONVEYORS. The Merrick Weightometer (Merrick Scale Manufacturing Company, Passaic, N. J.) for weighing material in transit consists of (1) a part of the upper run of the belt suspended from counterbalanced weighing levers and (2) a totalizer driven by the moving belt which continuously multiplies weight by travel to give tonnage passing over the conveyor. This is recorded on a counting machine or chart recorder.

STEEL BELTS. The Sandvik belt (Sandvik Steel, Inc., New York) is a tempered, polished, cold-rolled steel band, about $^1/_{32}$ in. thick, made up to 32 in. wide and up to 375 ft long. It runs flat over rollers, spaced 6 to 12 ft, or slides on wooden strips. These belts handle clinker, phosphate rock, sugar, clay, foundry sand, and similar wet, sticky mixtures that do not discharge clean from fabric or rubber belts. They discharge either over the head pulley or by scrapers over the belts. The scraper is simple, cheap, and works well with materials that cannot be discharged cleanly by a belt tripper. The belts are light, run quietly, and when supported on rollers are said to take less power than rubber belts on troughing idlers. Belts wider than 32 in. can be made by a method of longitudinal jointing.

STEEL MESH BELTS are used for conveying through acid or alkaline baths, chemical solutions, and scalding tanks, and in processes of drying, baking, annealing, spraying, etc., for which fabric belts would be unsuited. They are made in the United States by Cambridge Wire Cloth Company, Cambridge, Md., and Wickwire-Spencer Steel Company, New York. They consist of woven wire mesh, with or without edge reinforcement, or of coils of wire interlocked and flattened. Sometimes the coils are joined over wire rods which may be bent at the ends to form a protective edge or border. These belts can be made of copper, brass, or the various alloys which impart strength or resist heat, corrosion, or the action of chemicals. They can be made with steel plate selvages or partitions that will bend around driving drums. Belts can be woven up to 12 ft wide. Those made for lehrs and annealing ovens will work regularly in temperatures over 1000 F.

LONG-DISTANCE CONVEYING BY BELT. See pp. 26-12 and 26-37. For an installation (Jeffrey Manufacturing Company) of long, wide belts of large carrying capacity, see Ref. 10.

17. SCREW CONVEYORS

Screw conveyors consist of a helical blade of metal fastened to a central pipe or shaft, and set in a trough or box. The blade generally is of steel plate, but, depending on service and nature of material handled, it can be cast iron, cast steel, or an alloy that resists corrosion and oxidation. The trough generally is U- or V-shaped with a rounded bottom. Some materials can be conveyed through a round pipe if the length is short enough to permit the screw conveyor bearings to be kept outside the pipe.

Bearings are of various kinds, babbitt, bronze, chilled cast iron, hardwood. Success with screw conveyors often depends on using the proper kind of hanger bearings and the right kind of trough. It is advisable to consult the makers on these points.

CONVEYING CAPACITIES. Figure 16 shows curves developed by Link-Belt Company, Chicago, for capacities of screw conveyors. Diagonals 3, 4, 6, etc., are diameters of screw, in inches. Curves *A*, *B*, *C*, etc., are advisable speed limits, rpm, but rating should be multiplied by a capacity factor *X*, values of which follow.

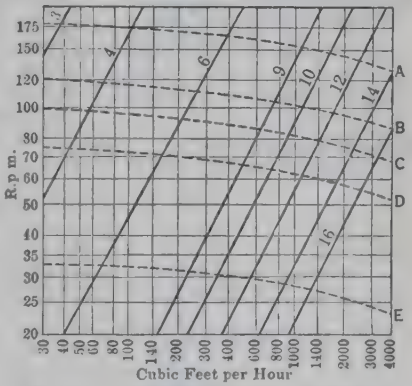

FIG. 16. Capacities of screw conveyors.

Class 1. Dry, free-flowing, not gritty; as grain, malt, flour, meal, pulverized coal; advisable speeds not beyond curve *A*; $X = 1.00$.

Class 2. Shelled corn, clean cottonseed, fine coal, crushed ice, pulverized minerals that are not abrasive; advisable speeds not beyond curve *B*; $X = 0.75$.

Class 3. Wet malt, starch, sawdust, ground cork, carbon black, dry paper pulp stock, nonabrasive minerals, with occasional lumps (not over 25%) of size not over $^1/_8$ diameter of screw; advisable speeds not beyond curve *C*; $X = 0.66$ to 0.75.

Class 4. Damp, trashy cottonseed, dry clay, raw sugar, foundry sand, fertilizers, crushed gypsum, lime, and other abrasive materials with lumps (not over 50%) of size not over $^1/_6$ diameter of screw; advisable speeds not beyond curve *D*; $X = 0.50$ to 0.66.

Class 5. Very gritty materials, as ashes, wet or dry, silica sand, pulverized flint or quartz, flue dust, fly ash; advisable speeds not beyond curve *E*; $X = 0.30$ or less.

The capacity factor *X* refers to screw conveyors with intermediate hanger bearings. If conveyor is short, has no hanger bearings, and is properly fed, capacity may be 50% greater than use of the factor would indicate.

Screw conveyors at slopes up to 10 or 15 degrees have about the same capacity as level conveyors. At greater slopes, capacity tends to fall off, but for such conditions, screws with short-pitch flights can be used. Screws at steeper angles should be referred to the makers. Vertical screws, run at the proper speed and properly fed, will elevate ground cork and some other light materials in closed pipes. In "batching" plants that serve concrete mixers, Link-Belt vertical screws have been used to elevate cement 20 or 30 ft. They require more power than a bucket elevator and are likely to get out of order from cement working into the step bearing. The advantage is that they are light and portable.

HORSEPOWER OF SCREW CONVEYORS. If a screw conveyor is crooked and out of line, if speed is excessive, if hangers and bearings are not suited to the work, if discharge outlets choke, the power consumed cannot be estimated. For screws working under proper conditions, Link-Belt Company gives the following general formula:

$$\text{Hp} = 1 + \frac{ALN + CWLF}{1{,}000{,}000} \qquad (1)$$

where L = length of conveyor, feet; N = rpm of screw; C = cubic feet conveyed per hour;

W = weight of material, pounds per cubic foot; A and F are factors. For conveyors with lubricated bearings, values of A are:

Diam. of screw, in.	3	4	6	9	10	12	14	16
A	15	21	33	54	66	96	135	186

For bearings not lubricated, multiply A by 1.75; for chilled iron bearings, multiply A by 2.5.

Factor F varies with kind of material (see classification under Conveying Capacities), and within a given classification with the resistance material offers to moving in the trough and past hanger bearings. Values of F are:

Material class	1	2	3	4	5
F	0.4–0.6	0.4–0.9	0.6–1.2	1.4–2.0	2.0–5.0

For specific values of F, see Link-Belt Company catalog.

SCREW CONVEYOR FEEDERS. For withdrawing material from a bin at a definite and regular rate, a screw has these advantages over other feeders: (1) compact, leak-proof, dust-tight; (2) relatively cheap in first cost and operation; (3) can be fitted to bin bottoms of any shape; (4) acts as a shut-off valve as well as a feeder.

Figure 17 shows a short feeder of diameter A in a closed pipe for the length D. The pipe prevents material from flooding out of the bin and acts as a shut-off when screw is idle. Screw is tapered over length C, which is attached to the bin, and the trough is flared. Diameter B is one size smaller than A. The screws are made with heavy steel blades on heavy pipe. Table 8 gives dimensions of the three sizes used for feeders. The carrying capacity for fine material, or material containing not more than 25% of lumps, is about 0.02 cu ft per revolution for 9-in.; 0.04 cu ft for 12-in.; and 1.1 cu ft for 16-in. screws.

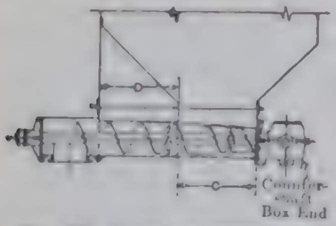

FIG. 17. Screw conveyor feeder.

Table 8. Dimensions of Screw Conveyor Feeder

Size of Conveyor, in.	Max. Size of Lumps, in.	Dimensions, in. (See Fig. 17)			
		A	B	C	D
9XX	1 1/2	9	6	24	24
12XXX	2	12	9	36	36
16XXX	2 1/2	16	12	48	48

For longer feed screws, where an intermediate bearing must be used, sizes are either 9 in. or 12 in. A U-shaped trough is used beyond the length D (Fig. 17). It contains the hanger bearing and a screw of full diameter. Clearance between screw and inside of trough should be 3 to 4 in. Length $D + C$ has a screw of a reduced diameter B. The rated capacity is the same as for short feed screws, but the lumps may be 50% of total volume.

For cement, pulverized coal, and materials which at times flow like fluids, screw feeders are inclined upward at 20 or 30 degrees, with outlet of the trough higher than the intake point. Screws generally have double flights.

THE THRUST IN SCREW CONVEYORS should be taken on end castings. These are of various kinds, with ball or roller thrust bearings for heavy loads. Driving ends with bevel gears are general. The Link-Belt Company places the motor worm gearing and oiltight gear box on a base plate; gear box is bolted to end of the trough.

TROUGHS are well standardized. For cement and similar dusty materials no attempt is made to bolt on a dust-tight cover. The cover plate is flanged downward all around and rests in grooves formed by Z-bars on top edge of trough. Dust collecting in the grooves seals cover against further dust emission.

Screw conveyors originally were used for conveying grain, but their use has been greatly extended. With properly designed screws, troughs, bearings, and drive ends, they handle a wide variety of materials, some of which cannot be conveyed by any other kind of conveyor. For details of screw conveyors and accessories, see catalogs of makers of conveying machinery.

18. PNEUMATIC AND HYDRAULIC CONVEYING

PNEUMATIC TUBE CONVEYORS are used for transmitting small carriers between departments of shops, newspaper offices, industrial plants, etc. The conveyor tube is round or oval, the carriers are short, of a cross section to fit the tube, and are propelled at 20 or 30 ft per sec by vacuum or air pressure. The round tubes are 1 $^1/_4$ in. in diameter or larger; the oval tubes are 3 by 6 or 4 by 7 in. Short lengths of small tube, up to 200 ft, can be served by a foot-power pump, but usually a motor-driven blower is used. For a history and description of this system, see Ref. 11.

PNEUMATIC CONVEYING FOR BULK MATERIAL was first used in England, developed chiefly in Germany, and now finds extensive use in the United States. The suction or vacuum system (Fig. 18) comprises an exhauster or pump to produce a partial vacuum, a pipe line through which mingled air and material move, a receiver or cyclone to separate the material from the air, and usually a bag filter to clear the air and keep dust from the exhauster, and prevent its discharging to atmosphere. In a pressure system, the pump delivers air to a pipe line. Material is fed from a supply bin through an airtight rotary valve into the pipe, moves with the air to a cyclone or separator. The air is discharged to a filter or to atmosphere. The material settles to the bottom of the cyclone.

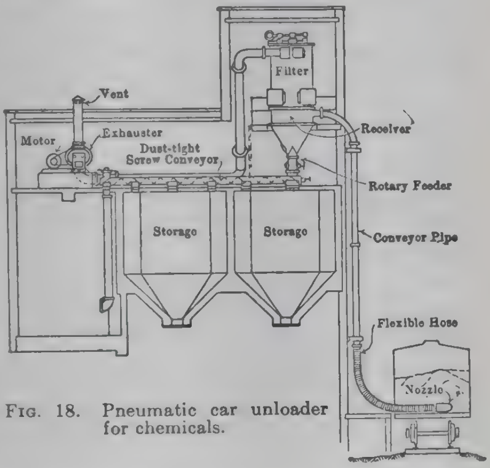

FIG. 18. Pneumatic car unloader for chemicals.

Carrying capacity depends on amount of air pumped and difference in air pressure between the two ends of the system. Theoretically, almost any material can be conveyed, but feasibility and cost are determined by practical considerations. (1) Material too large requires large-diameter pipes and a large air pump. (2) Material too dusty may require too large a filter. (3) Material too fragile may be reduced in value by breakage at pipe turns, or dust produced by breakage may require a costly filter. (4) If air pressure is kept low enough to avoid damage to material or to avoid excessive wear at pipe turns, carrying capacity may be too low to be economical.

The cost of a pneumatic system may be higher than that of a mechanical system. Power cost may be five or ten times as much, but a pneumatic system often is justified by other considerations. (1) In boats, a flexible suction hose is more easily handled than an elevator leg, takes up less room, cleans up better, requires less shoveling, can work under closed hatches in wet weather. (2) In unloading railroad box cars, time often is saved, labor costs reduced, delays and demurrage charges avoided. Avoidance of dust sometimes is important. (3) In handling bulk materials in manufacturing plants, labor often is saved, less dust is produced, and less space occupied. Changes in the pipe system to reach new points of intake or discharge are not difficult, and, what often is most important, conditions of safety and health for workmen are better.

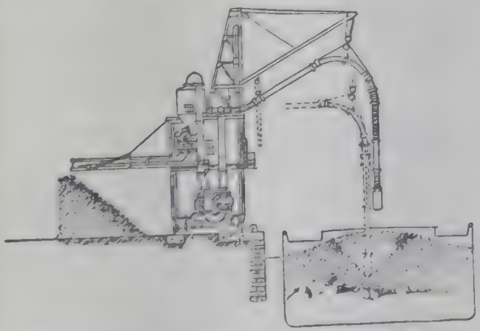

FIG. 19. Fuller pneumatic conveying system.

A combination of pneumatic handling with mechanical conveying often is desirable. In Fig. 18 material is drawn from the cyclone separator to a distributing screw conveyor. At the New York State Barge Canal terminal in Brooklyn, grain is lifted 80 ft vertically from barges, and discharged to a distributing belt conveyor.

Figure 19 shows a Fuller conveyor system on a movable tower for unloading small-size soft coal at a cement plant. Coal, at rate of 100 tons per hour, passes through the cyclone separator, is discharged to a short belt conveyor, then dropped on the ground to be distributed later over the storage area by a drag scraper. The tail pulley of the drag line is attached to the rear of the tower and moves with it. See Drag Scraper System, p. 26-10. The boat also carries cement in bulk from the cement plant. At destination, the cement is unloaded by a Fuller-Kinyon pump system on the boat. See below.

Pneumatic systems for conveying bulk material are made by Dust Recovery and Conveying Company, Detroit, Brady Conveyors Corporation, Chicago; Federal Pneumatic Systems, Inc., Chicago; Holly Pneumatic Systems, Inc., New York; United Conveyor Corporation, Chicago; Fuller Company, Catasauqua, Pa.

SUCTION SYSTEMS for collecting and conveying chips and sawdust from woodworking machines and dust from grinders are made by B. F. Sturtevant Company, Boston; Allington and Curtis Manufacturing Company, Saginaw, Mich.; Kirk and Blum Manufacturing Company, Cincinnati, and also by makers of blowers and exhausters. A Kirk and Blum installation in Camden, N. J., handles over 1,000,000 cu ft of air per min, collects 150 tons of sawdust daily, and has filters with an area of 200,000 sq ft of cloth surface. Similar systems for taking ground coal, rock, etc., from pulverizing mills are made by several makers of grinding mills.

For precautions against fires in blower systems, see publications of National Fire Protection Association, Boston. For safety codes for preventing dust explosions, see Ref. 12.

GRAIN UNLOADING. Suction apparatus for unloading grain from boats is used at many ports in Europe. The whole system, including power plant and separators, generally is mounted on a barge or float that works on the harbor side of the ship. It transfers grain to river barges while the ship discharges other cargo on the wharf. In the United States, one of the largest suction systems for unloading grain is the one in Brooklyn mentioned above; it lifts 6500 bushels per hour. At the public grain elevator, New Orleans, where it was necessary to provide for a 21-ft range of water level, and for boats differing greatly in width of beam and depth of hold, a pneumatic unloader of 6000 bushels per hour capacity has been used since 1917.

THE FULLER-KINYON CONVEYING SYSTEM (Fig. 20) is not strictly a pneumatic conveyor. At one end of a pipe line a short impeller screw 1 is driven by motor 2. Material is fed through hopper 3. At discharge end of cylinder in which the screw revolves, compressed air enters through rings 4 and 5. The material when mixed with air acts as a fluid. In the fluent condition it is forced through the pipe line 6 by the displacement of material fed in by the screw and also by the expansion of the compressed air used to create the fluent condition.

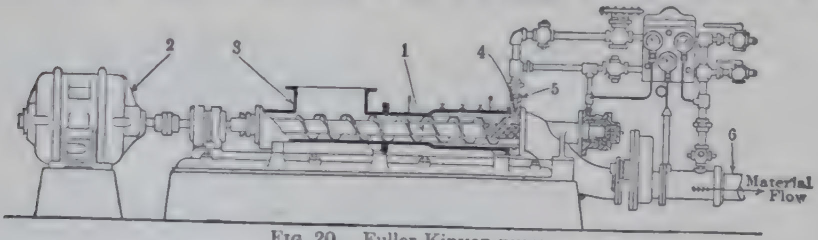

Fig. 20. Fuller-Kinyon pump.

Practically any dry pulverized material in quantities up to 300 tons per hour can be transported by this system over distances of 3000 ft and elevations of 150 ft or more. The system is widely used in cement mills, and for other pulverized materials as lime, soda ash, starch, kaolin, bauxite, etc. The pipe line may range from 2 to 8 in. in diameter according to amount of material. Branch pipes are connected to the main line by two- or three-way valves, usually operated by hand, but sometimes by automatic and remote control. Bins can be filled in desired sequence; the system will continue to work automatically so long as any bin has room to receive material. Deliveries under automatic control have been made to 48 bins in one system. To mix and blend raw materials in cement making, the discharge from several pipe systems may be controlled automatically according to predetermined time intervals. Hot materials up to 1000 F are successfully conveyed. Pipe lines may be water jacketed for cooling cement in process of manufacture. Steam-jacketed lines also are in use.

Figure 21 shows a Fuller-Kinyon portable pump, used chiefly on construction jobs to unload bulk cement from box cars or barges, to convey it to mixer bins or storage, and to reclaim it from storage to the bins. The pump is a motor-driven self-contained unit. Clutches control the power drive to the traction wheels. Cement is discharged through flexible hose which may be connected to any of the steel pipes leading to delivery point.

Several boats on the Great Lakes are equipped with the L. D. Smith system of drag scrapers (see p. 26-11) and a Fuller-Kinyon pump. Cement is pumped ashore at rate of 1400 barrels per hour through a flexible hose to the pipe lines which distribute cement to silos or pack houses.

The Fuller-Kinyon system often is cheaper and more convenient than any combination of mechanical elevators and conveyors. For short distances power consumption may be more, but for average or long distances it is likely to be less. Its advantages are that pipe can be run anywhere over, under, or around obstacles; and that material conveyed is always enclosed so that risk of fire, explosion, or injury to workmen is low. For temporary jobs of road making or building construction, its erection, dismantling, and moving are relatively cheap.

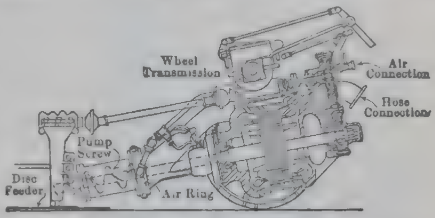

Fig. 21. Portable Fuller-Kinyon pump.

TRANSFER OF MATERIALS UNDER DIRECT PRESSURE. The Fluxo pump (F. L. Smidth & Company, New York) is used in some cement plants to transfer cement or dry pulverized raw materials to and from storage bins. A carriage runs on a track at one side of a row of silos or storage bins, and connects with a pipe in the base of the silo by flexible hose. On the carriage are two tanks, a vacuum pump with an air filter, an air compressor, and an electropneumatic control apparatus. When the current is being drawn into one tank by suction, it is being expelled from the other by air pressure. The operation is reversed by the control apparatus, the tanks alternately filling and emptying. The flow, from silo to transport line to which the machine is connected, is continuous.

The Kennedy transport system consists of a single tank, to which cement or other pulverized materials flow, suitable valves, air under pressure, and a transport pipe line. At a predetermined weight of material in the tank, springs on which the tank rests deflect, the supply is shut off, the bottom valve opens, and air admitted to top of the tank forces the material out through the pipe line. The cycle automatically repeats.

STEAM-EJECTOR SYSTEM FOR BOILER-HOUSE ASHES. The Steamatic ash-conveyor system has in many cases replaced the steam-jet system of handling ashes. In the Steamatic system, air flow is produced by a ring-nozzle ejector and a venturi tube placed at the discharge end. These claims are made: (1) Low steam consumption. (2) Relatively little wear on pipe lines and pipe turns. (3) Since ashes are in contact with steam for only 3 ft of travel, they enter the bin dry, and do not pack, or freeze in winter. (4) Less noise. (5) No danger of explosion in storage bin. This system requires steam at 70 psi or higher, will carry up to 200 tons of ashes per day up to 300 ft distance, and lift through 100 ft. Pipes are 4, 5, 6, 8 in. in diameter. The 8-in. size handles large clinkers and is most economical of steam per ton of ashes carried. Small pipes may be used as branch lines for fly ash and soot.

The Nuveyor system is similar in principle to the Steamatic. The pipe line is the same, but to produce suction a positive air exhauster of the Roots blower type or a multijet exhauster is used. In both cases ashes pass to a cyclone separator; then by an automatic timing device, which acts every 90 seconds, a release valve opens, suction stops for 5 seconds, and ashes in the cyclone drop into the storage bin. Figure 22 shows such a system with an air washer between cyclone and exhauster. No dust enters the latter, and discharge to atmosphere is clean. The air washer acts also as a silencer. The Nuveyor will handle 30 tons of ashes per hour, is quiet in operation, and ashes entering the storage bin are dry. The system is operated by remote-control buttons at points where ashes are fed to pipe line.

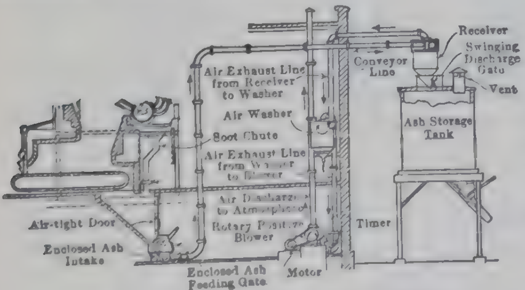

Fig. 22. Nuveyor system of ash handling.

ASH DISPOSAL BY WATER FLOW. In the Hydrojet system ashes accumulated under boiler furnaces are dislodged by a water jet at 100 psi and moved through a trench below the basement floor by similar jets. Figure 23 shows the system applied to the ash pit of a chain grate stoker. The whole apparatus is enclosed. The jet breaks down the pile of ashes; the mixture of water and ashes flows into the trench under the floor, lined with U-shaped cast-iron plates; nozzles at intervals deliver jets in the direction of flow.

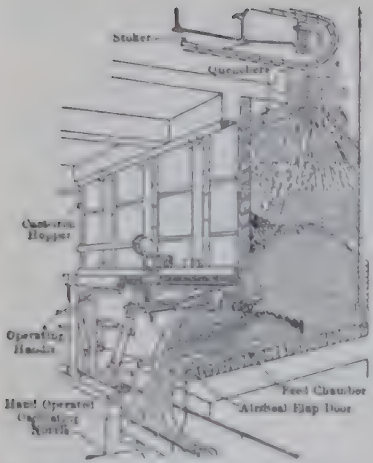

FIG. 23. Hydrojet system of ash removal.

Outside the boiler house the discharge can flow to waste land or to a sump from which ashes are removed by grab bucket or pumped to a drainage bin for removal by car or truck. Advantages claimed for this system are: (1) No escape of dust, gas, or steam into basement. (2) Men cannot be gassed or burned. (3) No leakage of air from basement into furnace to disturb combustion. (4) Operation is intermittent; time is available for repairs when necessary. (5) Overhead ash hoppers and cars are not used; boiler house can be built 10 ft lower.

The Hydrovac dust-handling system for boiler houses removes siftings under stokers, fly dust from boiler settings, soot and floor sweepings, by means of air flow under vacuum produced by high pressure water jets in a venturi tube. The siftings can be blown into a furnace, refuse can be collected in a tank for removal or discharged into the water trench of the Hydrojet system.

For mechanical methods of ashes handling, see p. 26-35. For hydraulic ash handling systems, see Ref. 13.

19. PACKAGE HANDLING

TYPES OF PACKAGE ELEVATORS. (1) For boxes, barrels, bales, and sacks, the rigid-arm elevator (Fig. 24) will discharge over head wheel only. (2) The automatic-arm elevator (Fig. 25) has carriers arranged to lift and lower; lifting side is so hinged that it will dump a barrel or sack forward when a lever on the arm contacts with an adjustable cam on the lifting side of elevator. On lowering side, the arm is rigid. Packages going down are deposited on skids at unloading point. (3) Suspended tray elevators (Fig. 26) have trays so hung on pivots between two chains that center of gravity of loaded tray is well below points of suspension. These trays, when made with finger bottoms, will pick up packages from skids on the up run and deposit them on skids on the down run. Solid-bottom trays require loads to be put on or taken off by hand. Suspended tray elevators run at not over 30 ft per min. (4) Elevators with corner-hung trays (Fig. 27) are similar to (3) but the chains are not directly opposite each other and pivots are not in line. This makes tray more stable in passing around turns and on straight runs, but wheels are out of line and the drive is not so simple. (5) Tray elevators with selective discharge: Style A, long trays with fingered bottoms with one loading compartment for each discharge point; receiving fingers at each floor are set to register with com-

partment for that floor. Style B, fingered trays dumping forward on up run; tray guides have a throw switch at each floor to tilt the tray; switches being controlled by latches on tray which are set by an indicator at loading point.

. Package elevators in these various styles are made by nearly all builders of conveying machinery. Much ingenuity has been spent on special forms. Elevators are made for trays of dishes, to deliver to or to take from roller conveyors, and for selective discharge.

PACKAGE CONVEYORS. (1) Packages of uniform size, not too heavy, can be moved in a trough by pushers which are attached to a single moving chain. (2) Packages can be carried on slats which slide on both runs. (3) Slat conveyors moving on roller chains will handle packages of any size or weight. Discharge is generally over the end, but movable plows can be used to deflect boxes sideways for intermediate discharge. (4) Belt conveyors are used in shops, assembly departments, stores, post offices, etc., for handling stacks of light package goods of all kinds. For this work the conveyor has straight tubular idlers, and the edges of the belt are supported to prevent sagging between idlers. Figure 28*A* shows the construction with steel guards used in department stores, the goods being delivered by chute from above. Figure 28*B* shows the construction where packages are tossed on the belt from below. For light work the belt may slide on a hard wood plank. (5) Packages of uniform size can be carried long distances and at any angle of slope by wheeled carriages attached to a single moving chain. (6) Inclined conveyors generally are used for handling and piling bags and bales. They have a belt to which cleats are attached, or else push bars mounted on two strands of chain.

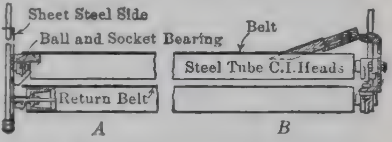

Fig. 28. Belt conveyor for packages.

Package conveyors are built by all makers of conveying machinery. For information concerning them and special conveyors to work with gravity roller systems, see catalogs of the several makers. Selective discharge from belt or roller conveyors is described by W. O. Hildreth, Ref. 14. For selective discharge actuated by photoelectric relay, see Ref. 15. The electrical apparatus is made by General Electric Company.

A novel form of portable flexible conveyor for goods in bales and sacks is the Twinveyor (Clark Tructractor Company, Battle Creek, Mich.). It comprises several 8-ft sections coupled end to end by flexible joints. Each section is made of two parallel tubes 4 in. in diameter geared together and driven by a 5-hp motor, with a blunt screw thread on the outside. As the screws revolve, the bag or bale resting on them acts as a nut and travels at 90 ft per min. The original installation is described by J. T. Buzzo, Ref. 16.

THE MONORAIL CHAIN CONVEYOR consists of a power-driven chain suspended from trolleys on a continuous track, usually overhead. The chain joint pins are in a vertical plane. It bends around sprocket wheels or nests of rollers, or it can bend around tracks curved in a vertical plane if the proper chain is used. Loads are carried on hooks, racks, trays, slings, etc., hung from the trolleys. Speed generally is less than 75 ft per min. The chain may be in one plane or several. It may serve several floors of one building or connect several buildings. Work can be done on suspended pieces as they travel along to dipping vats, baking ovens, etc. Monorail chain conveyors do work for which floor trucks and freight elevators otherwise would be required. They occupy no floor space, require little power, and provide a steady movement of parts from one operation to another and to final assembly, inspection, and shipment

Calculation of Monorail Chain Conveyor.* (1) Make a layout, and scale off amount of chain required. (2) Assume a chain speed and a spacing of loads, as determined by time required to travel a certain distance, or the number of pieces to be delivered per minute. (3) Sketch tray or carrier and make the horizontal and vertical turn so that carriers clear each other even if they swing. (See Fig. 29.) (4) From catalogs of makers select a trolley suitable for the load. These have been standardized. (5) As a first approximation, assume horsepower pull for a single-plane conveyor to be 5% of total moving weight (chains, trolleys, carriers, loads), about 7% for a conveyor with a few easy vertical curves, and 10% for one with many curves. (6) Select a chain strong enough for (5), and suited to the trolley. (7) Locate drive where sprocket wheel has at least a 90-degree arc of contact with chain; 180 degrees is better. The take-up should be where chain is under light load. Vertical turns work best if chain passing them is not under heavy tension. (8) For more accurate determination of chain tension and horsepower, calculate chain pull

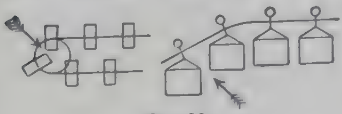

Fig. 29.

---

* Adapted from Link-Belt *Data Book*.

for each run and each turn. Thus, $C_H = WLX$; $C_C = YC$, where W = weight of moving parts, pounds per foot, empty or loaded as the case may be; L = length of run, feet; X = 0.03 for ball- or roller-bearing trolleys; = 0.05 for bronze-bushed trolleys; C_H = pull for each straight horizontal run, pounds; C_C = pull for each corner, take-up idler or roller turn in horizontal plane, pounds; C = chain pull at turn, pounds; Y = 0.03 for sprocket wheel or roller turn; = 0.02 for a traction wheel turn. The pull for a double curve in passing from one level to another is

$$C_V = WSX + CZ + HW$$

where W and X are as above; S = horizontal length of double curve, feet; H = height of double curve, feet, taken as (+) when travel is up, (−) when travel is down; C = chain pull at entrance to the curve, pounds; Z = friction factor due to radial pressure of trolley on curve, for ball or roller bearings Z = 0.001 per degree of inclination from the horizontal of tangent between curves, for bronze-bushed trolley wheels, Z = 0.002. (9) To algebraic sum $C_H + C_C + C_V$, add 5% for friction at drive wheel. Check this against strength of chain, assumed in (6). (10) The radial pressure on each trolley is $P = BC/R$, where B = trolley spacing, inches; R = radius, inches, to center of chain on curve; C = maximum chain pull at any curve, pounds. Check this with permissible trolley load. If too great, space trolleys closer or make radius longer. The longer the radius, the better the operating results.

Where conditions make it difficult or impossible to drive a chain by a sprocket wheel, an auxiliary drive acting on the straight run of chain may be used. The auxiliary chain is short and has pushers which engage links of the conveyor chain. The Webb system of using a number of these devices synchronized, and with automatic speed control, is described by H. C. Rundle, Ref. 17.

ROLLER CONVEYORS will readily convey down slopes of 1 1/2 to 5%, boxes, packages, cans, bottles, lumber, steel products, almost anything that has a smooth face or side. The goods travel over rollers of steel tubing fitted with ball bearings. Capacities range from a few pounds up to 4 tons per roller. Some conveyors have spaced wheels instead of rollers. Rollers are assembled in straight sections, curves, switches, Y-assemblies, and roller spirals. They can be set on floors supported from walls or hung from ceilings. Roller conveyors have been highly developed and have a wide field of usefulness. For a description of an elaborate system of Logan Company conveyors with a new form of switch, see C. K. Pevear, Ref. 18.

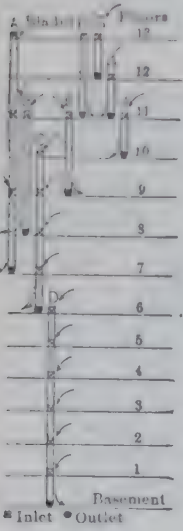

FIG. 30. Scheme of spiral conveyor system.

SPIRAL CHUTES are made by manufacturers of roller conveyors. Some are made with roller beds, others have steel plate bottoms. They carry boxes, packages, and even some kinds of unwrapped goods from upper to lower floors. Some are made with two or more spirals. They provide means for delivering different classes of goods to separate unloading stations at the lowest floor of a building, or goods can be passed from one floor to another on one spiral without interfering with goods on other spirals. Figure 30 shows diagrammatically a chute with six spirals serving thirteen floors of a clothing factory. The letters A, B, C, D, E, F indicate separate spirals, and the arrows show inlets and outlets. G, H, and J are straight chutes in the system, not part of the spiral chutes, but all combine to provide a gravity flow for raw materials from the thirteenth and eleventh floors to manufacturing floors below, and finally as finished goods to the shipping room in the basement.

PROCESSING OVENS. Monorail and other forms of chain conveyors are used to carry cores, lithograph plates, and enameled metal parts through drying and baking ovens, and to carry metal parts through ovens in which they are dipped and drained. Other forms of processing ovens are equipped with roller beds for handling cores and other parts on pallets. Some carry the work on trays suspended from two chains.

The conveyor tunnel kiln conveys tile, refractory brick, and similar ceramic materials through a firing kiln by means of rocking frames which support the materials. In other forms of the kiln, castings, steel plate, or other heavy materials are annealed while they move through the kiln on a train of cars propelled by a ram.

VEHICLES

20. TIERING MACHINES, LIFT TRUCKS, SKIDS, AND PALLETS

TIERING MACHINES (portable elevators, stackers) for piling case goods, barrels, bales, rolls of paper, etc., are made in a variety of styles and sizes. These machines also are used to handle dies to the level of press beds, put up and take down overhead motors and shafting, build riggings and platforms for painting, cleaning, and repair work, etc. For light service and occasional use, they are operated by hand crank, fitted with a safety brake to prevent it from flying back and injuring the operator. For regular service, an electric-driven machine is more useful.

Figure 1 shows a hand-powered stacker for lifts from 4 to 12 ft. The frame is hinged so that the machine can pass through a doorway. Smaller hand-powered and electric machines are made with telescoping frames for 2000-lb loads and 12-ft lifts. Most of the electric machines are driven by extension cables to a power source, but models are also available which are self-contained power units, driven from electric storage batteries (Fig. 2). These have advantages over the extension cable type for portability and maneuverability.

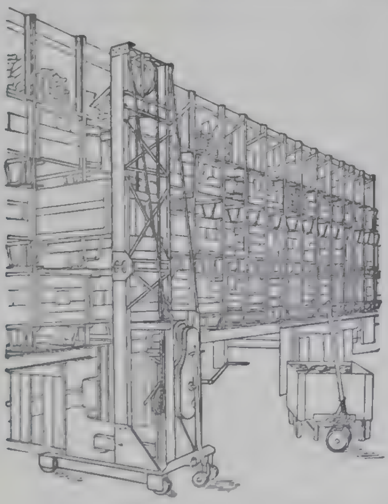

Fig. 1. Hand-powered stacker.

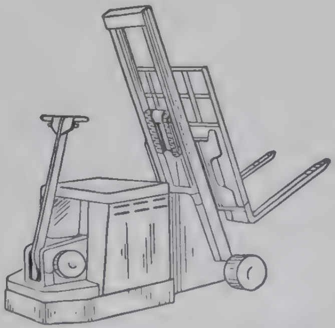

Fig. 2. Yale battery-powered industrial tilting-fork portable elevator.

One manufacturer builds these units with a turn-table in the base (Fig. 3), which permits the platform or uprights to be turned in the complete 360-degree circle. This type of unit has certain advantages in tight locations in narrow aisles.

The hinge type, or telescoping lift type with single uprights, is generally limited to a lift of about 18 ft, and 2000-lb capacity; but other units have been built with multiple uprights, the platform riding between end supports similar to a freight elevator.

Units have also been built in what is known as the box type, that is, one box frame telescoping inside the other like a set of toy blocks; and these units have been built to elevate to a height of 96 ft for window cleaning, building maintenance, repairs on aircraft motors, etc.

SKIDS AND PALLETS are related in principle but are of different construction. That is, they are accessories for lift truck operations, and involve the principle of a movable floor, as they provide sectional areas to pile materials on so that these materials can be handled in unit loads.

Skids. The skid platform, or skid (Fig. 4), is a flat rectangular platform, made of wood or metal, and elevated a short distance above the floor, resting on longitudinal members, skid legs or casters, or a combination of legs and casters. There are several types of skid platforms, built in standard widths from 24 to 54 in., and in standard lengths from 24 to 96 in., both in light- and heavy-duty types. The most common type has steel legs and a hardwood surface. Skid platforms are manufactured in two standard clearance heights, from floor level to inside of skid platform, namely 8 and 12 in. This type of skid can be handled either by hand lift truck or power lift truck. The minimum horizontal width between the inside of the runner legs or other supports is 29 in. when the skid is to be handled by power lift trucks. Platform skids are generally classified under the following types:

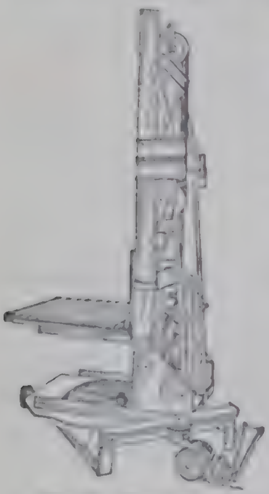

FIG. 3. Revolvator.

1. Dead skid, which means a skid with fixed legs or runners.
2. Semi-live skid, which means a skid with two fixed legs at one end, and two rigid casters or wheels at the other end (Fig. 5).
3. Live skid, which means a skid equipped either with four rigid casters, one at each corner, or with two swivel casters at one end, and two rigid casters at the other.

The construction of the skid depends on the nature of the load. The capacity of the skid depends on the strength and stiffness of the top platform and the type of supporting members. If the loads are evenly distributed over the entire surface of the platform, the skid has more capacity than if the weight is centrally concentrated. Too concentrated a load may cause the platform to sag. Excessively long or wide loads require additional support for the skids on the sides or the ends. Skids must be of the proper capacity for the loads to be handled. An undercapacity skid platform is unsatisfactory in service, is frequently in the repair shop, and has a short life.

Since the underside of the platform skid must be left clear for the entry of the lift truck, the legs or support members must be located near the outer ends, and must also be close to the ends to prevent tipping. When not supported by the lift truck, the load is carried on the top of the platform skid, the side angles and the supporting legs, casters or other members. For that reason, the capacity of a very long or very wide platform is much less than that of a short or narrow one, even though the angles and top members are of the same thickness. Thus the capacity of a skid platform varies inversely with its length and width. Also, because of the construction of the platform, uneven or springy floors require stronger skids, as the weight of the load must at times be carried on two or three legs. This feature makes it difficult to stack skid loads one on top of the other, unless they are placed in racks or with sufficient dunnage to spread the load over the top of the load beneath. Many varieties of special platform superstructures are built by manufacturers to meet specific operating conditions. This includes such features as superimposed removable boxes, fixed shelves and racks, removable vertical posts at sides or ends, and special attachments for particular commodities.

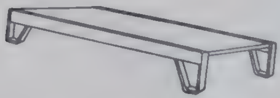

FIG. 4. Steel frame skid.

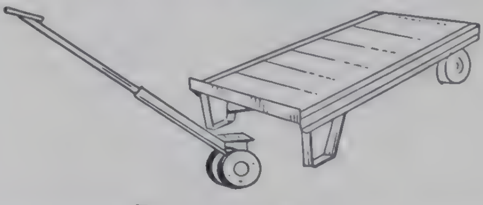

FIG. 5. Semi-live skid.

Skids can also be built that do not require a lift truck. These are generally constructed with two wheels in the back and two legs in the front. A separate handle fitted with wheels is thrust under the leg end of the platform (Fig. 5) and either engages a pin or a plate mounted on the front end of the platform. When the handle is pushed down, the front of the platform is lifted. The weight is taken off the legs, and the platform is ready to roll. However, in the majority of installations, some type of lift truck is used for handling skids.

Pallets are different from skids and can be constructed of a variety of materials, such as metal, paper, soft and hard woods, and are either open faced or double faced. The term *face* means the surfaces, top and bottom.

The most common type is of hardwood construction, with three stringers. The top and bottom boards are full lengths, and spaces are provided in the lower deck so that the pallet can be handled by pallet trucks as well as power fork trucks.

Pallets have been made with steel stringers and wooden decks, and also of all steel construction, especially for handling hot materials. They are classified under three general types, regardless of the material used in their construction:

1. Open-faced pallet with stringers mounted to an upper deck only, and with no lower deck.
2. Double-faced pallets (Fig. 6), constructed with stringers between an upper and a lower deck, with openings in the lower deck to provide space for the drop wheels of the hand pallet truck; generally approximately 3 $^1/_2$ to 3 $^3/_4$ in. is required for clearance between the upper and lower deck for operation with hand pallet trucks or power fork trucks.
3. Box pallets, constructed of a framework with one or more open sides and mounted on standard pallets so as to provide for handling of small, odd-size, or crushable items; the box frame is to provide supports for multiple stacking.

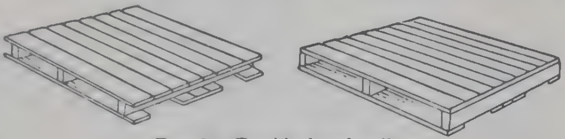

FIG. 6. Double-faced pallets.

Pallets are made in a wide variety of sizes. In stating the measurements, the length of the pallet is always the dimension in the direction of the stringers or the distance required for the length of the forks or trucks, even though this dimension might be shorter than a width dimension, which is the length in the direction across or at right angles to the truck center line.

In building pallets a number of handling operations should be taken into consideration so as to locate the stringers properly, as these can be placed at the extreme edge of the top and bottom deck. If, however, the pallets are to be handled by slings from cranes, ships' gear, or other similar handling, the stringers should be set inboard approximately 3 $^1/_2$ in. from each side of the end of the top and bottom deck.

The double-faced pallet (Fig. 6) has been found to be the best unit to use for most commodities when they are being placed in storage, because it provides a good load distribution on the lower tiers.

Various attachments for standard pallets and special pallets can be built, as for skid platforms.

The advantages of handling goods on skid platforms or pallets include saving in time and labor, avoidance of loss or damage from piecemeal handling, and facility in handling and storing in large units without breaking bulk. Indirect advantages are simplified cost and inventory accounting, and greater mobility of stores, supplies and materials.

The paper and other industries are now shipping goods on skids or pallets, in what are known as unit loads. Advantages of unit load shipments include all the advantages of intra-plant unit load handling, plus savings in packing material, labor cost of handling and unloading, and elimination of breaking bulk in rehandling. Savings actually may range from 25 to 90%.

HAND-LIFT TRUCKS for handling skids are made in three or four styles, depending on the manufacturer. Some of these units have hydraulic lifts operated by a pull handle, which raise the skid platform to clear the floor 3 in. or more (Fig. 7). In some instances, this is done with step-by-step ratchet lift operated by the handle (Fig. 8); some are known as foot-lift models, worked by a foot treadle.

The principle of the truck is the same, but they differ chiefly in lift and release mechanisms. These trucks are generally constructed with forward wheels, connected to a steering handle, which is attached to a main frame, in which the rear wheels are mounted. A second framework is imposed upon the bottom framework, and, through a system of linkage, it is possible to raise the skid and its load from the floor.

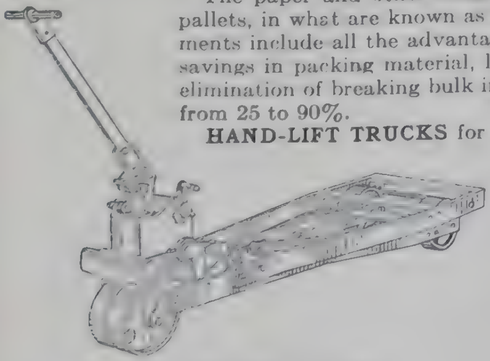

FIG. 7. Hydraulic-lift truck.

When fully elevated, this lifting frame assumes a fixed position and remains rigidly locked in place until released by the operator. In order to avoid shock, the lowering of the load is generally accomplished through a powerful hydraulic check.

HAND-PALLET TRUCKS operate on the same principle as the hand-lift truck, being constructed with large forward wheels connected to a steering handle, and attached to a main frame, but the rear wheels are small and are depressed in the main frame (Fig. 9). At the end of the main frame, near the back, additional small wheels are mounted which assist the operator in propelling the fork end of the truck into the pallet, in the opening between the stringers.

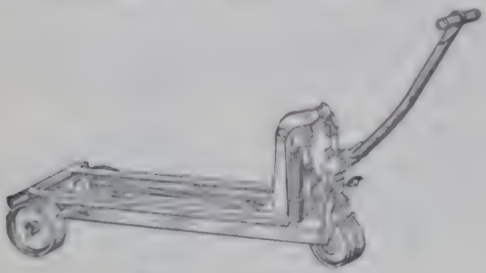

Fig. 8. Jack-lift truck.

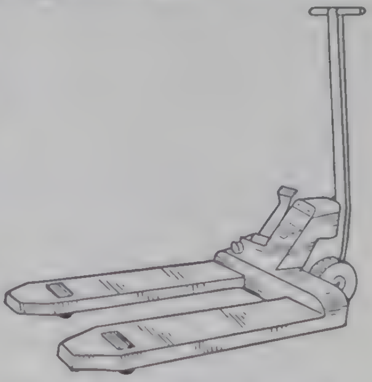

Fig. 9. Hand-pallet truck with hydraulic lift.

With double-faced pallets, great care must be taken to space the openings in the bottom deck so that these small wheels can pass through these openings, in order to raise the pallet off the floor for transportation. This lifting is accomplished as in the hand-pallet truck, and the lowering of the load is also accomplished in the same way.

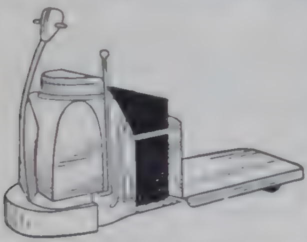

Fig. 10. Hand-controlled power-operated lift truck.

In addition to hand-propelled and hand-operated lift trucks and pallet trucks, there are now trucks of this same type with electric power to assist in the transportation operation, and in some instances for elevating the load (Fig. 10). These trucks are constructed with practically the same type of main frame as the hand-pallet trucks, but the front wheels are driven by an electric motor which receives its current from a storage battery located directly back of the steering handle. By using push-button control type electric contacts, mounted in the steering handle, the operator is able to control the forward and backward movement of the truck by applying power as desired.

21. INDUSTRIAL TRUCKS AND TRACTORS

TRUCKS WITH FIXED PLATFORMS are generally called *burden-carrying trucks.* They are power operated and can be built with either a high or a low platform (Fig. 11). They load and unload manually or by auxiliary equipment. They are built in different capacities. Some are constructed with drives at both ends, and with a low-slung platform in the middle section such as is used in baggage service in railroad stations; others are built in the high-type platform, with the platform 20 to 24 in. above the ground, with the wheels arranged either for two-wheel steer or four-wheel steer. In the majority of cases, they are electric storage battery operated.

Because they have a fixed platform, it is necessary to load and unload these trucks either manually or with auxiliary equipment, such as a crane mounted on the truck itself, or operating beside it. They are not as efficient for general handling as the elevating platform truck or a fork truck.

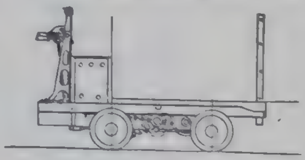

Fig. 11. Electric platform truck.

TRUCKS WITH LIFT PLATFORMS, generally known as *elevating platform trucks,* are of two sorts: low-lift elevating platform truck and high-lift elevating platform truck. They are made in capacities of 2000 to 20,000 lb.

In low-lift trucks (Fig. 12) a cam or link motion in the base frame raises the platform to give floor clearance, only sufficiently to raise the skid from the floor for transportation

In high-lift trucks (Fig. 13) the platform is raised by cables or chain, by a screw working in a movable nut, or by hydraulic cylinders. These trucks are designed with platforms to handle standard skids as well as special or higher skids.

The wheels under the platform of these low-lift and high-lift trucks are seldom over 10½ in. in diameter, and roughness and unevenness of floor affect them more than trucks with larger front wheels.

In the high-lift elevating type of platform, the front wheels or supporting wheels sometimes offer interference when an attempt is made to place the raised load on to platforms, trucks, trailers, etc. However, these front wheels make it possible to have a short truck, as little or no counterweight is required, since the load on the uprights is partially supported by these front wheels.

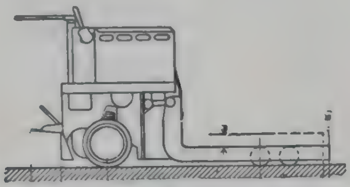

Fig. 12. 2-ton electric elevating platform lift truck.

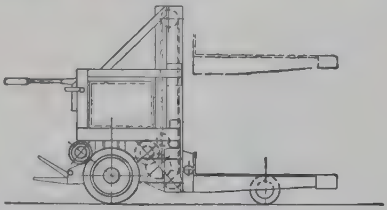

Fig. 13. 3-ton electric high-lift elevating platform truck.

FORK-LIFT TRUCKS are a modification of the low-lift and high-lift elevating platform truck, except that these trucks are built on a cantilever principle, and therefore require considerable counterweight back of the drive wheels, in order to compensate for the load cantilevered in front of the uprights (Fig. 14).

Fork-lift trucks are of either the telescoping or nontelescoping type, are generally provided with a forward and backward tilt, and are built in capacities of 2000 to 30,000 lb. The load is supported in front of the vertical uprights, and the tines or forks project either into pallets which support the loads, or directly under unit loads for stacking or handling.

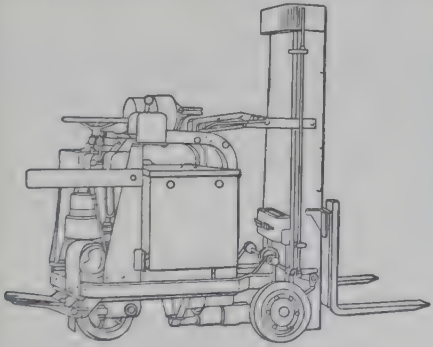

Fig. 14. Fork type lift truck.

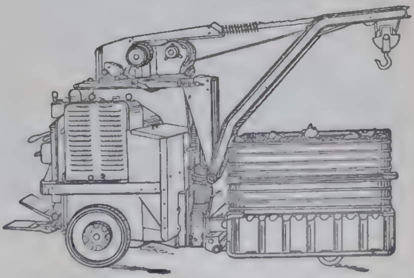

Fig. 15. Electric lift truck with crane.

Fork trucks are sometimes called chisel trucks, if they are equipped with very thin forks or steel plates for chiseling under a load, without the need of supporting the load on a pallet.

They can also be equipped with rams for picking up cylindrical materials, and with a wide variety of attachments for clamping the load, for turning it over, for tipping it forward, etc., in which cases they are sometimes given trade names or called by the name of the accessory, such as a *ram truck*. The proper term for this type of truck is a cantilever truck.

OTHER TYPES OF INDUSTRIAL TRUCKS are rigid boom, industrial cranes, swinging boom, etc. These are made up as special units or sometimes mounted on low-lift industrial trucks or burden-carrying trucks (Fig. 15). It is better to use a distinct unit for this type of operation rather than a combination unit.

The rigid boom industrial crane is small and compact, mounted on a tractor or a specially designed chassis with the boom suspended in front of the power unit and with sufficient counterweight to keep the unit from tipping (Fig. 16).

In some models, the boom can be topped to different angles into fixed positions, but not while the load is being carried. In other models, the boom is power topped and can be raised or lowered with the load suspended from the hook.

The swinging boom industrial type of crane is constructed in the same way, and in some models the boom is mounted on pedestals above the power unit, and counterbalanced with weights so that it can swing in a full 360 degrees.

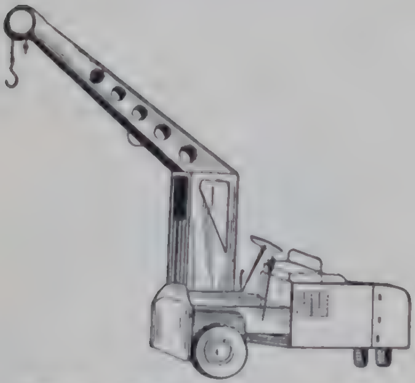

FIG. 16. Rigid boom industrial crane.

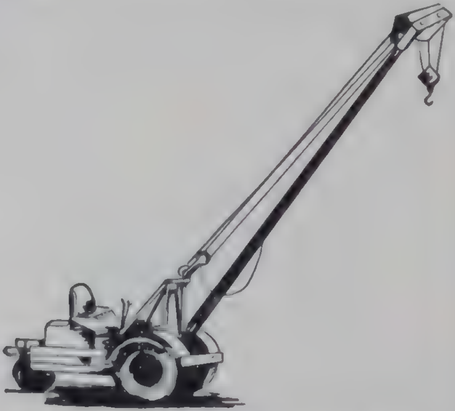

FIG. 17. Swinging boom industrial crane.

In other models, the boom is mounted over the drive wheels, and is attached to a vertical mast, so that it can swing up to 300 degrees (Fig. 17). Suitable counterweights are provided on the side of the tractor units to prevent tipping.

The various types of industrial trucks that are power operated are generally powered by electric storage batteries, or gasoline-electric generator units, or straight gasoline power.

Some manufacturers mount all their models on solid rubber tires; other manufacturers mount all their models on pneumatic tires. Some manufacturers have a combination of pneumatic tires and solid rubber tires. The pneumatics have distinct advantages when used over rough ground, uneven surfaces, and to eliminate vibration on the equipment and the load.

INDUSTRIAL TRACTORS are built in a variety of sizes and with different wheel combinations. The capacity is figured by drawbar pull. Some industrial tractors are built with crawler-type treads. On outside work, the usual cleat type crawler is acceptable, but for use on finished roads and floors, crawlers equipped with rubber pads to prevent damage to the surface are required.

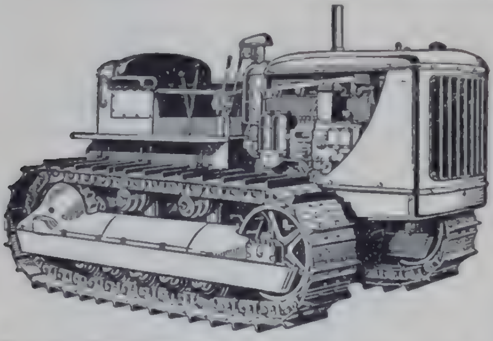

FIG. 18. Track type tractor. (Courtesy, Caterpillar Tractor Co.)

Tractors can be broken down into three classifications:

1. Crawler tractors, which are tractors without wheels and supported on a self-laying crawler type of tread (Fig. 18).
2. Three-point contact tractors, which have three points of contact with the road surface, the drive being through the two wheels at the rear and the steering by the front wheels (Fig. 19). The front wheels can be either a single or a dual wheel, placed close together.
3. Four-point contact tractors, which are driven by the rear wheels, and have two steering wheels, spaced wide apart, at the front, similar to an automobile (Fig. 20).

The size and type of tire and the weight of the unit have a direct bearing on the tractive effort, and the drawbar pull or capacity of the tractor.

These tractors can be operated either by electric-storage battery, electric-generator sets, or straight gasoline. Tractors are recommended where the quantity of materials handled is enough to warrant the use of trains of trailers, and where movements of trains can be arranged according to a time schedule or a route schedule.

The selection of the size of tractor will depend on the trailers to be hauled, the length of the train, the grades to be negotiated, the type of service on which they must operate, and the speed of operation.

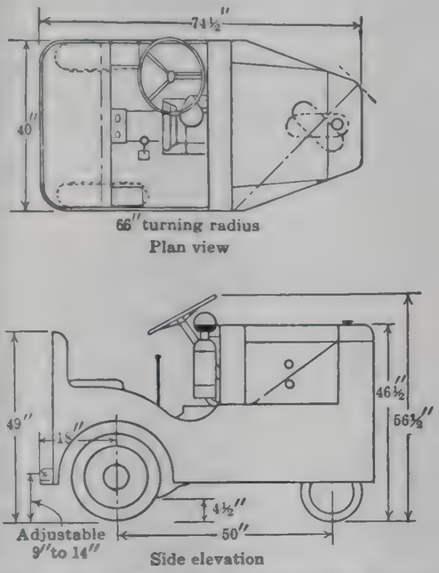

FIG. 19. Three-wheel industrial tractor. (Courtesy, W. F. Hebard and Co.)

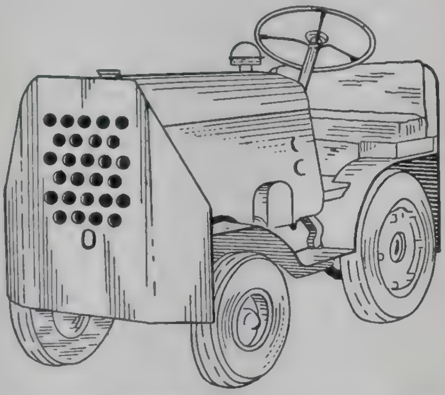

FIG. 20. Four-wheel industrial tractor. (Courtesy, W. F. Hebard and Co.)

22. INDUSTRIAL TRAILERS

Industrial trailers, which are used in combination with industrial tractors, are made in four types: four-wheel steer; caster; fifth wheel (wagon); and balance type. Table 1 can be used for selecting trailers for particular operations.

Table 1. Cars and Trailers for Different Services

Moved by	Conditions and Loads	Style of Car (*See* Note)		
		Choice		
		1st	2d	3d
Power	Accurate trailing	A	B	C
Power	Accurate trailing and reverse	A	D	....
Power	Good or rough runways, heavy loads on 2 or 3 trailers	C	A	D
Power	Good runways, heavy loads on 4 or more trailers	B	A	C
Power	Rough runways or dirt floors, heavy loads on 4 or more trailers	C	A	......
Power	Rough runways or dirt floors, light loads	A	C	......
Power	In conjunction with considerable hand trucking	B	C	D
Hand	Good runways, light loads	B	D	C
Hand	Poor runways, dirt floors, heavy loads	C	...	.....

Note. A—4-wheel-steer trailer; B—Caster trailer or truck; C—Fifth-wheel trailer or truck (wagon-type); D—Balanced trailer or truck. On right-angle turns in 7 ft aisles, caster trailers will creep outward 3 or 4 in.; fifth-wheel, 7 to 10 in.; balanced trailers with cross-chain connections, 7 to 10 in.; 4-wheel steer trailers will not creep. The larger the radius of turn, the less the creep.

Four-wheel steer trailer (Fig. 21) is a unit with all wheels of the same type, with front and rear axles mounted on fifth wheels, or the wheels mounted on knuckle steers, and all four wheels coupled together through cross reaches or linkage so that they steer simultaneously. On these trailers, the drawbar is removable so that it can be connected to either end of the trailer.

A four-wheel steer trailer is different from a reversible trailer, because on a four-wheel steer trailer, the front and rear axles are linked together at all times, and all four wheels steer simultaneously. This four-wheel steer makes for accurate trailing, but requires a larger radius for turning than the caster type.

When the trailer-train is pulled away from a platform or curb, the train must be steered gradually so as not to bind the wheels against the platform or curb obstruction. This difficulty is encountered because of the tendency for the second trailer, etc., to steer sideways from the trailer in front.

A reversing trailer has four wheels of the same size and the axles are mounted on fifth wheels at each end of the trailer. The drawbars are removable, but the wheels are not connected together, and, in operation, one end of the trailer is locked in position to make that pair of wheels rigid.

Caster trailers (Fig. 22) are constructed with the rear wheels on rigid axles, and these are larger than the steering wheels, which are mounted in swivel casters at the front end of the trailer. On this type of trailer, the drawbar is mounted at the front end of the platform, and the couplers on the rear end of the platform.

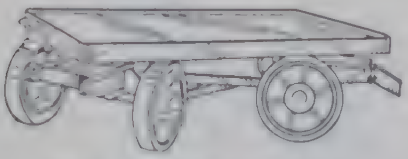

Fig. 21. Four-wheel steer trailer.

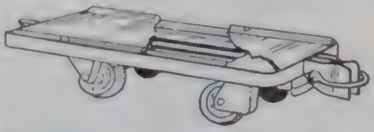

Fig. 22. Caster-type trailer with automatic coupler.

The average caster-type industrial trailer is built in capacities of 2 to 3 tons, and generally with a platform 3 ft wide by 6 ft long, of wood and steel construction, although some have been built with platforms 4 ft wide and 8 ft long, of all steel plate construction. The rear or rigid axle is generally located about one-third forward of the platform, and thus the large rear wheels carry about two-thirds of the load. This relieves the weight on the caster wheels, which are located near the front of the trailer, one on each side, making it easier for the casters to swivel under the load. This type of trailer moves easily, steers well, can be maneuvered in narrow aisles, and can be moved by hand if necessary. They are generally equipped with automatic couplers but can be equipped with hook and eye type or cross chain type, if desired.

Fifth-wheel or wagon-type trailers (Fig. 23) are used for heavy loads on rough surfaces, and they are not reversible. They are generally constructed with all four wheels of the same size, although in some instances, the rear wheels are slightly larger than the front or steering wheels. The rear wheels are mounted on rigid axles, and the front wheels are mounted on an axle attached to a fifth wheel steering arrangement, with the drawbar attached directly to the front axle and the fifth wheel. The steering unit is mounted on a single king pin with a large bearing plate, and in some instances, these are made with an oscillating arrangement to allow the front wheels to conform to the unevenness of road surfaces.

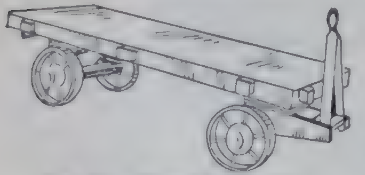

Fig. 23. Wagon-type trailer.

Balance-type trailers are like warehouse hand trucks, and carry the load on two large wheels mounted in the middle of the trailer; they have single or double casters at each end. This type of trailer turns easily by hand but does not trail well at high speeds.

On smooth new floors, trucks and trailers with steel wheels start easier and roll easier than rubber-tired wheels; but on most floors, on runways, ramps, and paved yards, the rubber-tired, canvas cushion wheels or pneumatic tired wheels have the advantage. The pull is less, goods are not shaken or damaged, wear and tear on the truck is less, noise is reduced, and damage to floor is eliminated.

In every case, trailers should be equipped with anti-friction roller bearings, and where dust or dirt is prevalent, these bearings should be protected with dust seals and should be fully enclosed in order to reduce wear, tear, and maintenance.

It is important to consider the height of the platform from the roadway so as to eliminate excessive lifting, but care should be exercised to see that the wheels are not too small for the service required.

Trailers, like pallets and skids, can be equipped with dump bodies, removable bodies, special rack bodies, etc., and these will be found to have advantages for handling specific materials.

CONDITIONS OF FLOORS AND RUNWAYS. The tractive resistance of trailers is affected by the type of floors. Table 2 gives the resistance in pounds per ton for various types of road surfaces. For each 1% of upgrade, add 20 lb per ton.

Table 2. Tractive Resistance of Various Surfaces

(*Reprinted by permission from Materials Handling Cyclopedia, Simmons-Boardman Publishing Corp.*, 1921, p. 545)

Type of Road Surface	Resistance, lb per ton
Smooth brick	30 to 50
Concrete	28 to 40
Poor concrete	45 to 65
Granite blocks	50 to 60
Wood blocks	30 to 50
Gravel road, good condition	75 to 85
Clay	200 to 400
Wood planking	35 to 50
Wood planking, sticky surface	50 to 60

Tests made on trailers fitted with roller bearings and solid rubber-tired wheels show that power required to keep them moving varies greatly. Incidental disadvantages of poor floors and runways are:

1. Tractor operator will run slowly to prevent goods from being jolted off trailers.
2. Cost of repair and maintenance of equipment is increased.
3. Labor cost due to delays and stoppage is increased.

On rough floors, the advantages of anti-friction bearings tend to disappear, especially at speeds over 3 miles per hour.

It has been found on good floors that the rolling resistance of 8-in. wheels fitted with roller bearings is four times that of 20-in. wheels.

TYPE OF POWER FOR INDUSTRIAL TRUCKS AND TRACTORS. There has been considerable discussion of the type of power to be used for industrial trucks and tractors, without any general agreements. In arriving at a formula for estimating these costs for a specific installation, it is necessary to take into consideration the following factors.

For electric trucks and tractors, consider:

A. Depreciation of the electric truck.
B. Depreciation of storage batteries for that truck.
C. Depreciation of charging equipment.
D. Interest, maintenance, and storage charges.
E. Electric current for charging batteries.
F. Labor and cost of space, for charging batteries.
G. Maintenance and repairs of truck.

On gasoline units, consider:

A. Depreciation of the gasoline truck.
B. Interest, maintenance, and storage charges.
C. Maintenance and repairs of truck.
D. Gasoline and oil.

These costs will vary considerably, depending on the number of hours per day that the equipment is required to operate. The factor of depreciation can be made to vary because electric trucks can be shown to last 25 years, whereas gasoline trucks will have a life of approximately 10 years. However, it is best to figure the truck life on the basis of 5 years minimum and 10 years maximum, in both cases, as these trucks depreciate rapidly by obsolescence due to change in design and improvements in operational function.

It is claimed for electric trucks that:

1. They are quieter in operation.
2. They do not give off fumes.
3. They are therefore more advantageous for working in close and confined quarters.

It is claimed for the gasoline trucks and tractors that:

1. They can work 24 hr a day and take a fresh supply of fuel in 5 min or less.
2. The torque of the engine and the use of the clutch exerts a strong pull to start heavy loads or get over bad places in floors or paving.
3. They can go almost anywhere, are self-contained, and independent of power lines and charging stations.
4. They can travel over streets, public roads, bad floors, rough paving.

The ready-power gas-electric unit is a self-contained power plant for use on tractors and trucks designed for storage-battery power, where time cannot be spared for recharging. It is an automobile-type gasoline engine with automatic governor and generator armature instead of a flywheel. It will deliver 120 amp at 36 volts, or 90 amp at 48 volts. It weighs approximately 1000 lb and fits in the space required for a storage battery.

PROBABLE SAVINGS BY USE OF INDUSTRIAL TRUCK OR TRACTOR SYSTEMS. It is difficult to determine mathematically whether or not the use of any system of mechanical handling will be profitable. The Coes formula (Ref. 1) gives various debit and credit items which should be considered. If proper values are assigned, the justifiable investment and the probable profit based on the assumptions will be given by the formula. It may happen, however, that indirect savings will determine whether or not a materials-handling system will pay a profit. C. B. Crockett and H. J. Payne (Ref. 2) give explicit data on operation of electric industrial trucks and tractors in twenty plants. All show saving of time and money. In some plants, indirect and incidental advantages are most important. For examples of the use of the Coes formula, see Ref. 3. See also Ref. 4. *Materials Handling and Distribution* in March 1931, described a case where eleven tractors and twenty-three trailers, costing $27,000, saved $48,000 per year. The plant covered 40 acres, and all haulage was done on a time schedule. For other cases, see a list of fifty installations in the same magazine, Jan. 1930.

INDUSTRIAL RAILWAYS. For industrial plant railways, the usual gage is 24 in., although $21\frac{1}{2}$-in. gage is used in many places. Rails range from 12 to 25 lb per yard. Mill railroad is usually the standard 56-in. gage (4 ft $8\frac{1}{2}$ in.). This type of railroad, with fixed tracks, switches, and turntables, has been replaced in a number of industrial plants by industrial trailers, but they are still used extensively in mines, quarries, and on specific industrial operations.

In some instances, portable rail sections are used; they are generally made up in 15-ft sections, 24-in. gages.

Various types of locomotives are available, some using overhead wires, some third rails, others storage batteries. For mine work, the first are in most general use. They are low, four- or six-wheel structures, weighing 5 to 35 tons, for track gages as narrow as 18 in., and with one or two trolley poles. Two are used when rails are not bonded for the return circuit. Twenty-five-volt series motors generally are used. Haulage capacity, rated as drawbar pull, usually is taken as one-fifth of the weight of the locomotive, without excessive heating in the motor. The rating may be reduced to one-half the standard rating for steady work on long hauls or steep grades. The pull for mine cars on straight level track may be taken at 30 lb per ton; for grades, at 20 lb per ton for each 1% of grade. Usually speeds are 6 to 8 miles per hour.

These are the advantages of using storage-battery locomotives: It is unnecessary to bond rails or remove rock to make legal clearances for trolley wires. They are safe in gaseous mines, can place cars at the working face, remove loaded cars, and go wherever a track can be laid. If batteries are recharged at night, the day load of the power plant is decreased. For mine service, they are made in sizes up to 10 tons; for shifting railroad cars, size may be 50 tons.

Combination locomotives, fitted with both storage batteries and current collectors, also are built. Heavy-duty locomotives with diesel engine, generator plants, storage batteries, and current collectors for railroad switching works have been constructed.

Some operators prefer straight gasoline or diesel locomotives for certain types of haulage, as they are independent of power house, have large radius of travel, and as compared with steam locomotives, require less attention and use fuel only when working. (See Fig. 24.)

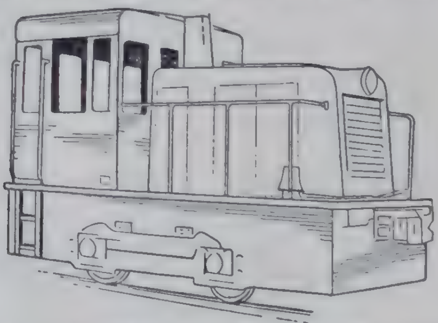

FIG. 24. Diesel-electric industrial locomotive. (Courtesy, General Electric Co.)

DUMPSTERS. This equipment, generally called a Dempster Dumpster, consists of demountable containers of various sizes and designs for operating on a special hoisting and dumping device, mounted on a motor truck chassis (Fig. 25), and recently installed on a tractor unit. The containers can be left in convenient locations for loading and unloading. It is a one-man operation to pick up the container, load it on to the truck, and transport it to the next operation. They have been used extensively in industrial plants for handling refuse, for specific handling operations, and in connection with construction work and city garbage disposal.

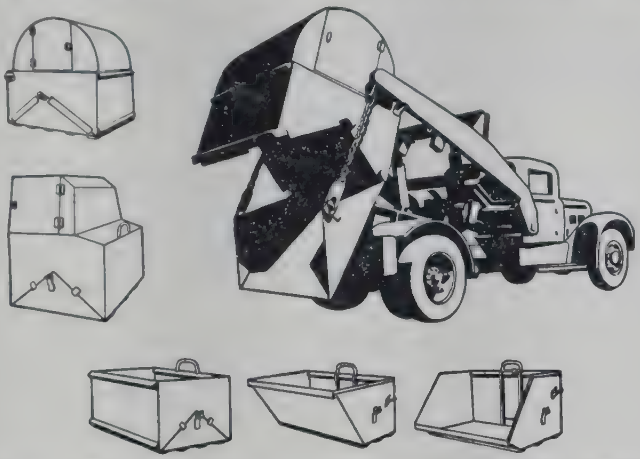

Fig. 25. Dempster Dumpster with various containers. (Courtesy, Dempster Brothers, Inc.)

OVER-THE-ROAD TRACTORS AND TRAILERS. For intraplant, intrastate, and interstate over-the-road handling, a two-wheel trailer, having its axles and wheels under the rear portion, and the frame supported in front on the fifth wheel of the vehicle that tows it, has many advantages, as it permits loading and unloading of the trailer chassis without tying up the expensive tractor unit. By using a motor transport trailer converter, which is a demountable fifth-wheel unit, for converting the semitrailers into full trailers, the same trailer chassis can be handled by either the "over-the-road" tractor unit, or any other vehicle capable of pulling the load.

MOTOR-TRUCK ACCESSORIES. Motor trucks are now a definite part of materials handling, both within industrial plants and between industrial plants. Therefore, it is essential to equip these units with the best possible loading devices.

The elevating end gate, which is a power-operated mechanism, replaces the tail gate of motor trucks, and is used for raising or lowering loads from the ground to the level of the truck platform or higher (Fig. 26).

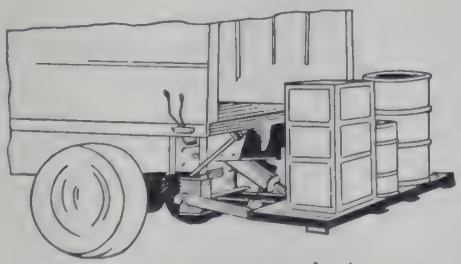

Fig. 26. Elevating end gate.

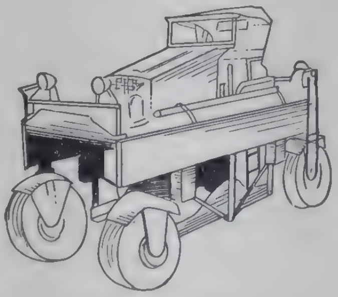

Fig. 27. Straddle truck.

Power winches for motor trucks, operating from the truck motor, facilitate the pulling on and lowering of loads too heavy to be handled by auxiliary equipment.

Demountable bodies for regular truck chassis have been found advantageous in a number of operations. They are supplied in standard units, and they can be designed to fit specific operations.

THE STRADDLE TRUCK is an automotive type of truck, with a four-wheel steer constructed on an inverted U-shaped framework (Fig. 27). The motor and the operator's position are on top of the framework, and the load is straddled, lifted, and carried suspended on hoisting shoes supported by the framework.

The straddle truck generally operates with bolsters under loads, such as lumber, steel, and pipe. They are also used in steel plants and shipyards, with special racks for steel plate from the storage yard to the fabricating shops; and with special bolster-type flat skid bodies, they have been used in industrial plants for handling a wide variety of materials.

These units are made in capacities of 10,000 to 30,000 lb, and with a speed of 30 to 50 miles per hour, so they can be used for internal plant service or over the highway.

Important dimensions to be considered in selecting the right type of equipment are width and height of load and length of bolsters supporting the load. Length of load is purely a matter of clearance for turning radius and balance.

BUILDING CONSTRUCTION

By Theodore Crane

The purpose of this chapter is to enable the mechanical engineer to make a reasonably accurate selection of the structural elements comprising a building, prior to the quantitative design, which would be developed later by a structural engineer.

1. BUILDING CODES: DESIGN STANDARDS

AUTHORITIES PROMULGATING BUILDING CODES. There is no national building code in the United States. Buildings erected for a department or agency of the federal government are designed in accordance with the standards of that department. Local building codes do not apply to structures erected on federal property.

There are only a few complete state building codes, but many states have passed statutes which apply to the design of buildings erected for particular uses. These state regulations affect particularly the design of factories, or other buildings where labor is employed, places of public assembly such as theatres, and multifamily dwellings. Some state labor laws and industrial codes specify minimum requirements for ventilation and sanitary facilities, as well as standards to safeguard employees from danger due to manufacturing processes or fires.

Many cities have building codes which apply to alterations or additions to existing buildings, and to all new construction. Often these codes are supplemented by separate ordinances promulgated by city departments, such as those for fire and health, which may also affect building design.

There are only a very few county building codes in the United States, but many townships have building ordinances which cover, much more briefly, the same subjects as the municipal codes. These township codes have very little significance, provided the designer follows standards of good practice, except in the matter of zoning.

ANALYZING BUILDING CODES. As there is a wide and unjustifiable variation in the approximately 2000 building codes now in effect in the United States, it is impossible to present any average of their specific requirements. There is, however, sufficient uniformity in the subjects which they control to permit a topical analysis. A primary necessity is that buildings be structurally adequate to meet the conditions of locality and occupancy. The design must provide a degree of protection from danger incident to fire, which is appropriate to size, location, and use of the building. Minimum standards are established for the health and safety of the occupants. Adding the subject of zoning, we have a substantially inclusive résumé of the topics covered by building codes, so far as they affect the architectural or structural design.

In the following paragraphs the contents of the more complete municipal ordinances are outlined. The outline is arranged in the form of a procedure to facilitate the checking of code regulations for any specific project.

Occupancy and Construction Classifications. Most city codes have five to seven classifications, based upon the type of occupancy, such as "Public Building," "Business Building," and "Residence Building." The identification of the classification is used in determining the allowable type of construction and in relation to zoning laws. Most city codes have about the same number of classifications based upon the type of construction. This classification is determined by type of occupancy, location in reference to fire limits, or zoning laws, and height and ground area of the structure. Regulations covering these matters appear in all building codes. Identification of the construction classification, such as fireproof and semi-fireproof, provides a minimum standard of fire resistance to which the design of the building must conform.

Zoning Laws. These laws may prohibit either extremely hazardous or otherwise objectionable types of occupancy, even within industrial districts. They also restrict the type of occupancy permitted in certain zones. In the more congested municipal areas, they may limit the perpendicular height of a building as a function of the width of the street or streets upon which it fronts. Some cities have definite height limitations for even fireproof structures.

Height and Area Limitations. Many building codes place a definite height limit for buildings of other than fireproof construction, particularly within "fire limits." Ground areas may also be limited for structures of the more combustible classifications when located within congested areas. Recommended limitations are given in Tables 1 and 2.

Table 1. Allowable Heights of Buildings

(From the *Building Code Recommended by the National Board of Fire Underwriters*)

Classes of Occupancy	Classes of Construction						
	Fireproof	Semifireproof	Heavy Timber	Ordinary	Light Noncombustible	Frame	Unprotected Metal
						Not permitted within Fire Limits	
Public * buildings	No limit	75 ft	Three stories nor more than 35 ft Churches: two stories nor more than 45 ft Schools: two stories Theatres †			Two stories nor more than 30 ft	One story
Institutional buildings	No limit	75 ft	Two stories nor more than 35 ft †			One story nor more than 35 ft †	One story
Residence buildings	No limit	75 ft	75 ft	Three stories nor more than 45 ft ‡	Three stories nor more than 45 ft	Two stories nor more than 35 ft Dwellings not to exceed three stories	One story
Business * buildings	No limit	75 ft	75 ft	Four stories nor more than 50 ft		25 ft	One story
Storage * buildings	No limit	50 ft §	35 ft §	35 ft §		One story nor more than 25 ft	One story

---

* Outside the fire limits public buildings, business buildings, or storage buildings may be erected to greater heights in the discretion of a board.

† Special occupancies: asylums, detention buildings, hospitals, penal institutions, orphanages, nurseries, and theatres hereafter erected shall be of fireproof construction or semi-fireproof construction; except that hospitals where occupants are not involuntarily detained or bedridden (sanatoriums) may be of nonfireproof construction, provided such buildings do not exceed two stories in height and the floors and partitions have fire-resistance ratings of not less than 1 hr, with fire-retardant ceilings under roofs. One-story theatres not over 30 ft in height may have wood or steel trusses and wood, steel, or gypsum roof decks if protected by fire-retardant ceilings.

‡ With a 2-hr first floor, height may be four stories or 55 ft; in multifamily houses with a 2-hr first floor and other floors 1-hr, with fire partitions subdividing floors into areas not exceeding 2500 sq ft, the height may be five stories or 65 ft.

§ Buildings which are sprinklered of semi-fireproof or heavy-timber construction may be 75 ft, and ordinary construction and light noncombustible may be 50 ft.

Author's note: Sprinklers are required by this code for certain types of occupancy.

Means of Egress. Except for single and two-family dwellings, the following matters are usually controlled by code: minimum hallway widths; location and design of stairs when serving as a required exit; location and design of fire towers and fire escapes, slope of ramps; number, location, size, construction, and operation of doors serving as required exits. In places of public assembly, width of aisles and arrangement of seats are definitely controlled.

Light and Ventilation. Minimum requirements often apply to the areas of windows and skylights; the areas of vent shafts and the widths of courts; the design of alcoves and the amount of mechanical ventilation.

Illumination, Wiring, and Electrical Equipment. Adequate lighting for safety, particularly in connection with exit facilities, is a general requirement of municipal codes. The light levels required upon working surfaces may be specified in state codes or state legislation applying to the employment of labor. The standards of the National Electrical Code and the National Board of Fire Underwriters are usually incorporated in building ordinances and should always be followed even if not mandatory.

Table 2. Allowable Areas of Buildings

(From the *Building Code Recommended by the National Board of Fire Underwriters*)

Maximum areas in square feet permitted in new buildings not protected by automatic sprinklers and without suitable subdivisions by fire walls for heavy timber, ordinary, light noncombustible, and frame construction or by fire partitions in fireproof and semi-fireproof construction.

Classes of Occupancy	Classes of Construction							
	Fireproof	Semi-fireproof	Street fronts *	Heavy Timber	Ordinary and Light Noncombustible		Frame	Unprotected Metal
					One story	More than one story	Not Permitted within Fire Limits	
Not a factor	Unlimited except as restricted by combustible occupancy		One street	6,500	6,000	5,000	5,000	Not restricted
			Two streets	8 000	7,500	6,000		
			Three streets	10,000	9,000	7,500		
			Four streets	10,000	10,500	9,000		

AREA MODIFICATION.

The limiting areas may be increased by 100% when the building is sprinklered, and by 200% when the building is sprinklered and does not exceed one story or an average of 25 ft in height to the roof, or to a fire-retardant ceiling through which there are no openings unless they open into shafts or ducts to the roof, the enclosing walls of which have the same construction as the ceiling.

Outside the congested areas of the city, when a hazardous condition is not created thereby, the area of a public building, a business building, or a storage building, not over two stories high, may be increased in excess of the areas fixed by this section, in the discretion of a board consisting of the chief executive officer of the municipality, the building official, and the chief of the fire department; provided that a building of combustible occupancy, or involving considerable combustible material in its structural parts, shall be sprinklered.

* Under this section a street shall be deemed to include any avenue, boulevard, street, alley, or lane, 20 ft or greater in width, or any court, parking space, or yard, with direct connection to a street, and not less than 20 ft wide. Such court, parking space, or yard shall be the property of the owner of the building and shall not be enclosed or roofed over.

Author's note. Sprinklers are required and further area restrictions established by this code for certain types of occupancy.

Plumbing, Heating, and Gas Piping. Minimum sanitary requirements applying to factories and to multifamily dwellings are often contained in state codes or state statutes. Municipal sanitary codes cover all types of occupancy. Subjects that should be particularly checked are number and type of fixtures; location and size of toilets, latrines or bathrooms, water tanks, and standpipes; regulations regarding sprinkler systems; fire-fighting equipment and automatic fire-alarm systems for high buildings. The more complete codes cover heat installations and heat appliances of all kinds, in so far as they are related to danger incident to fire. Safety provisions for the use of gas are customary.

Elevators, Escalators, and Dumbwaiters. The requirements for such installations cover design, construction, inspection, operation, and maintenance, but only a few matters apply to building design. Most important are regulations for elevator shafts and machinery compartments; size of elevator pits and penthouses; equipment loads and maximum slope of escalators.

Quality of Materials. These regulations often reflect local practice, but most large cities follow the standards of our national organizations, such as the American Society for Testing Materials. The recommendations of the National Board of Fire Underwriters are standard for all materials and appliances in so far as they are related to the fire risk.

Weights of Materials. All building codes contain a list of weights applying to various materials such as concrete, stone, and brick masonry. These weights are used in computing the dead loads required for design purposes.

Live loads and soil loads comprise floor, roof, sidewalk, and courtyard loads. Included also are maximum soil loads for different types of soil and rock; allowance for wind pressure; permitted reductions in live loads, and requirements for moving loads.

Working Stresses and Structural Limitations. Allowable, safe working stresses, applying to all structural materials, are given in all municipal building codes. Often they are supplemented by specific limitations which apply irrespective of stress requirements. Such might demand a minimum thickness for a wall or partition of a certain height, or a minimum thickness for a structural floor slab of a particular design.

Table 3. Minimum Design Dead Loads

(From *Minimum Design Loads in Buildings and Other Structures*, sponsored by the National Bureau of Standards, approved and published by the American Standards Association, 1945)

Walls	Pounds per Square Foot

Cypress, southern	32
Fir, Douglas, coast region	34
Oak, commercial reds and whites	45
Pine, southern yellow	39
Redwood	28
Spruce, red, white, and Sitka	28

Weights of masonry include mortar but not plaster. For plaster, add 5 lb per sq ft for each face plastered. Values given represent averages. In some cases there is a considerable range of weight for the same construction. These variations are given in the authority from which this table is abstracted.

Methods of Computation. Although most modern building codes follow the more recent standards recommended for structural design by our national engineering associations, it is often necessary to check the formulas and computation methods applying to structural design because variations still exist.

Construction Details and Standards of Workmanship. To insure structural adequacy and fire resistance, most building codes contain articles that cover such matters as the

Table 4. Minimum Live Loads of Representative Codes

(From T. Crane's *Architectural Construction*, John Wiley and Sons, 1947)

Type of Occupancy	Minimum Live Loads per Square Foot of Floor Area

* Does not apply to hotel lobbies, stairways, or any portion used for public assembly. Such spaces same as for office buildings.

† This requirement is often applied to the entire first floor irrespective of expected use.

‡ This requirement is usually applied to aisles between rows of seats.

§ Corridors, upper floors.

‖ Additional provision required for loaded trucks.

¶ Limited to 20,000 lb gross weight; minimum concentrated load, 8000 lb on an area 2 ft 6 in. square.

** Minimum concentrated load "at any point" 8000 lb.

†† One hundred for cars with loads less than 3 tons, 150 for trucks with loads 3 to 10 tons; 200 for trucks with loads above 10 tons; each classification also subject to maximum wheel concentrations.

‡‡ Any type of vehicle not exceeding 6000 lb gross weight; minimum concentrated load 4000 lb on an area 2 ft 6 in. square.

§§ These figures have significance only as minimums. Such structures should be designed for the actual loads due to the type of materials stored or manufacturing equipment.

‖‖ Or a series of concentrated loads of 300 lb each, spaced 3 ft 0 in. center to center, each occupying an area 1 ft wide by the depth of the tread, whichever will produce the greater stresses.

¶¶ Or a concentrated load of 8000 lb on an area 2 1/2 ft square placed in any position, whichever will produce the greater stresses.

bonding of masonry walls and riveting or welding structural-steel assemblies. To lessen the fire risk, there are generally regulations covering the minimum thickness of fire walls, partitions, and shaft enclosures; limitations in regard to the use of combustible materials in fireproof or semi-fireproof construction; thickness of concrete or other fireproofing material surrounding structural steel, or concrete reinforcement. "Fire stopping" is also specified.

LOADS CARRIED BY BUILDINGS comprise dead loads, live loads, wind loads, pressure due to earth or water, and in districts subject to earthquakes, lateral loads assumed to equal the probable effect of seismic disturbances.

Dead load identifies the weight of walls, columns, partitions, floors, roofs, and all otber permanent construction. In building codes, the dead load is controlled by stating the weights of materials which must be used in design. For example, 150 lb per cu ft for stone concrete and 120 lb per cu ft for brick masonry. Minimum design dead loads, abstracted from *Minimum Design Loads in Buildings and Other Structures*, sponsored by the National Bureau of Standards and issued by the American Standards Association as A58.1-1945, are given in Table 3.

Live load identifies all vertical loads except dead load but, in many building codes, it includes lateral loads such as are caused by wind. The live-load allowance represents the weight of the occupants, furniture, or other equipment, including stored materials or movable partitions. As applied to a roof surface it includes the allowance for snow. All municipal building codes designate specific live loads for the various types of occupancy. Table 4 gives minimum live loads of representative codes. These loads do not include any permanent parts of the structure.

It should be clearly understood that the loads shown in Table 4 are merely minimum live-load requirements. Their use does not relieve the designer of the responsibility of providing adequate structural strength to support safely the actual loads for which the structure is intended. This warning is particularly important for manufacturing and storage buildings. It will be seen that Table 4 makes no mention of a provision for concentrated loads except for garages. Such requirements have been omitted for the sake of clarity but appear in most codes as supplementing the uniformly distributed loads. For example, the floor of an office or storage building might be required to support a concentrated weight of 2000 lb, without other live load, on any area 2 1/2 or 3 ft square. Such regulations affect the design only if the stresses produced by such concentrations are greater than those due to the uniform load.

If roofs are intended for occupancy, they are designed to sustain the same loads as corresponding floor areas. If not intended for occupancy, an allowance varying from 20 to 40 lb per sq ft of horizontal projection is customary for flat roofs and those of moderate slope. Steeper roofs are designed for dead load, wind load, and a snow load appropriate for their slope and locality.

Live-load Reductions. Certain reductions are permitted in computing the total live loads carried by supporting members such as columns, but in no case should the total reduction be less than 50%. The following standard (Table 5) is abstracted from the *Building Code Recommended by the National Board of Fire Underwriters.*

Table 5. Maximum Permissible Live-load Reductions

	% Reduction
Carrying the roof	0
Carrying one floor and roof	0
Carrying two floors and roof	10
Carrying three floors and roof	20
Carrying four floors and roof	30
Carrying five floors and roof	40
Carrying six floors (or more) and roof	50

These percentages apply to live loads carried by columns, girders, trusses, walls, piers, or foundations. The Underwriters Code allows these reductions for all buildings except those intended for storage purposes, for which no reduction is permitted. Some codes permit lesser reductions for storage and manufacturing buildings.

Moving Loads. The dynamic effect of all moving loads should be considered. For example, the static loads on beams and girders supporting elevator machinery may be increased or the working stresses reduced.

Wind Loads. A minimum pressure in pounds per square foot is specified by all building codes as an allowance for the effect of wind pressure against exposed surfaces of buildings. Table 6, abstracted from *Minimum Design Loads in Buildings and Other Structures*, shows wind pressures for zones of various heights. The figures given are recommended in this report as minimums. These requirements do not provide for tornadoes because they are based on a design wind velocity of 75 mph, corresponding roughly to a 5-min average of 50 mph (indicated 63 by a 4-cup anemometer) at 30 ft from the ground.

Special provision for wind bracing is required for narrow buildings of even medium height and for all high buildings. In towerlike structures wind bracing should be planned in the early stages of design. The overturning moment due to wind pressure should not exceed two-thirds of the moment of stability, disregarding live loads, except where foundations are securely anchored. The possibility of a structure sliding on its foundation bed should also be considered. In computing the wind load no allowance should be made for the shielding effect of other buildings. All roofs should be designed to resist wind suction as well as wind pressure (Ref. 1).

Table 6. Design Wind Pressures for Various Height Zones of Buildings or Other Structures

(From *Minimum Design Loads in Buildings and Other Structures*, American Standards Association A58.1-1945)

Height Zone, ft	Wind Pressure, lb per sq ft
Less than 50	20
50 to 99	24
100 to 199	28
200 to 299	30
300 to 399	32
400 to 499	33
500 to 599	34
600 to 799	35
800 to 999	36
1000 to 1199	37
1200 to 1399	38
1400 to 1599	39
1600 and over	40

Earthquake Loads. In districts that have experienced earthquakes of an intensity of VII or over, in the Ross-Forel scale, adequate provision should be made in the design to resist the lateral forces caused by seismic disturbances. For an appropriate design procedure see *Minimum Design Loads in Buildings and Other Structures*, previously identified.

Soil Loads. The figures given in building codes for the allowable bearing values of various soils and rocks are merely somewhat arbitrary maximums and should be checked by subsurface investigation, often supplemented by a load test. As a guide in selecting reasonable soil-bearing values, Table 7 is abstracted from the Boston Building Code. Refer to Article 8 in this section, under Subsurface Materials, for further identification of these classifications (see p. 27-54).

Table 7. Allowable Bearing Values for Various Soils and Rocks

(Boston Building Code 1944)

Class	Material	Allowable Bearing Value, tons per square foot
1	Massive bedrock without laminations, such as granite, diorite, and other granitic rocks; gneiss, trap rock, felsite, and thoroughly cemented conglomerates, all in sound condition (minor cracks allowed)	100
2	Laminated rocks such as slate and schist, in sound condition (minor cracks allowed)	35
3	Shale in sound condition (minor cracks allowed)	10
4	Residual deposits of shattered or broken bedrock of any kind except shale	10
5	Hardpan	10
6	Gravel, sand-gravel mixtures, compact	5
7	Gravel, sand-gravel mixtures, loose; sand, coarse, compact	4
8	Sand, coarse, loose; sand, fine, compact	3
9	Sand, fine, loose	1
10	Hard clay	6
11	Medium clay	4
12	Soft clay	1
13	Rock flour, shattered shale, or any natural deposit of unusual character not provided for herein (value to be fixed by the commissioner)	

Table 8. Rated Fire-resistive Periods for Various Walls and Partitions

(From Uniform Building Code, Pacific Coast Building Officials Conference, 1946)

Material	Construction			Minimum Finished Thickness Face to Face (Including Plaster Where Mentioned), in.			
				4 hr	3 hr	2 hr	1 hr
Brick of clay, shale, sand-lime or concrete and plain concrete	Solid unplastered			8			4 *
	Solid plastered			9		5 *

	Plastered each side	5 *	4 *	4 *	3 *
Hollow wall of reinforced pneumatically placed concrete	Outer shell 2-in. thick for 10-in. wall and 1 1/2-in. thick for 8-in. wall.	10 *	8 *		
Solid gypsum or portland cement plaster	Incombustible studding with metal or wire lath				2 *
	Incombustible studding with metal or wire lath, neat wood fiber gypsum plaster			2 *	
Hollow stud partition with gypsum or portland cement plaster or pneumatically placed plaster on each side	Incombustible studding with metal or wire lath, 3/4-in. plaster on each side				3
	Incombustible studding with metal or wire lath, 1-in. plaster on each side			4 1/2	
	Wood studs with metal or wire lath. Fire-stopped. 3/4-in. plaster on each side.				3 * or 5
	Wood studs with metal or wire lath. Fire-stopped. 1-in. neat wood fiber plaster each side.			5 *	
	Wood studs with 3/8-in. perforated gypsum lath. Fire-stopped. 1/2-in. gypsum plaster each side.				3 * or 5

* Shall be used for nonbearing purposes only.

† 7/8-in. face shells.

‡ 8 in. for expanded slag.

RECOMMENDED WORKING STRESSES. During recent years, standardization of stress requirements has progressed considerably, but many building codes are out of date. The following references represent good practice. They have been widely accepted in current revisions of many building ordinances and are recommended as standards except when more restrictive requirements are mandatory.

Stresses for Structural Steel. *Specification for the Design, Fabrication and Erection of Structural Steel for Buildings*, contained in the manual entitled *Steel Construction*, published by the American Institute of Steel Construction.

Stresses for Reinforced Concrete. *Building Regulations for Reinforced Concrete*, adopted as a standard of the American Concrete Institute in 1941 and revised in 1947 (Ref. 2).

Design and Specification of Structural Lumber. *National Design Specification for Stress-grade Lumber and Its Fastenings*, recommended by the National Lumber Manufacturers Association.

Design and Specification of Masonry. *American Standard Building Code Requirements for Masonry*, identified as Miscellaneous Publication M174, National Bureau of Standards. It may be obtained from the Superintendent of Documents, U. S. Government Printing Office, Washington, D. C.

THE STANDARD FIRE TEST. The following procedure, given in more detail, appears in Appendix B of the Building Code Recommended by the National Board of Fire Underwriters. It prescribes a standard of exposure to fire of controlled extent and severity; in some cases the sample or assembly is immediately subjected to a fire-hose stream. Performance is defined as the period of resistance to such exposure elapsing before the first critical point in behavior is observed. If this period is 2 hr, the material or assembly, such as a partition or floor system, is given a "2-hr rating." These ratings vary from 1 to 4 hr, and they appear as requirements for the more fire-resistant construction classifications. It is consequently often necessary to limit the choice of structural assemblies to those having a rating consistent with the desired building classification. Typical regulations are shown in Table 8.

FIREPROOFING REQUIREMENTS. As the capacity of steel to support load is considerably reduced at such temperatures as may easily occur in any serious fire, adequate protection is essential for both structural steel and concrete reinforcement. Typical requirements, abstracted from the New York City Building Code, are given in Table 9.

Table 9. Thickness of Fireproofing to Protect Structural Steel Requirements for Various Fire-resistance Ratings

(From the Building Code of New York City, Amended to 1942)

Fire-resistive Materials	Minimum Thickness, in. 4 hr	3 hr	2 hr	1 hr
Brick	3 3/4	3 3/4	2 1/4	2 1/4
Brick	3 3/4	3 3/4	2 1/4	2 1/4
Concrete brick, block or tile, except cinder concrete units	3 3/4	3 3/4	2 1/4	2 1/4
Hollow or solid cinder concrete block and tile having a compressive strength of at least 700 psi of gross area	2 1/2	2	2	1 1/2
Solid gypsum block (to obtain 40 hr rating must be plastered with 1/2-in. gypsum plaster)	2	2	1 1/2	1
Gypsum poured-in-place and reinforced	2	1 1/2	1 1/2	1
Hollow or solid burned clay tile or combinations of tile and concrete	2 1/2	2	2	1 1/2
Metal lath and gypsum plaster	2 1/2	2	1 1/2	7/8
Cement concrete, Grade I	2	2	1 1/2	1
Cement concrete, Grade II	4	3	2	1 1/2
Cement concrete, Grade II, with wire mesh	3	2	2	1 1/2
Hollow gypsum block (to obtain 4-hr rating must be plastered with 1/2-in. gypsum plaster on outer side)	3	3	3	3

Grade I concrete is defined in this code as that in which the aggregate consists of limestone, traprock, blast-furnace slag, cinders, or calcareous gravel.

Grade II concrete is defined as that in which the aggregate consists of granite or siliceous gravel.

The fireproofing of reinforced concrete is obtained by specifying a minimum thickness outside the metal reinforcement. Table 10, showing typical requirements, is taken from the *Report of the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete*, 1940 sponsored by the American Concrete Institute, American Society of Civil Engineers and affiliated associations (Ref. 3).

Table 10. Thickness of Concrete Fireproofing to Protect Metal Reinforcement Requirements for Various Fire-resistance Ratings

(From the *Report of the Joint Committee on Recommended Practice and Standard Specifications for Concrete and Reinforced Concrete*, 1940, published by the American Society of Civil Engineers)

Structural Member	Minimum Thickness of Concrete, in. 4 hr	3 hr	2 hr	1 hr
Columns, beams, girders, and unprotected ribbed slabs				
Group 1, aggregate	1 1/2	1 1/2	1 1/2	1
Group 2, aggregate	2	1 1/2	1 1/2	1
Solid slabs				
Group 1, aggregate	3/4	3/4	3/4	3/4
Group 2, aggregate	1	3/4	3/4	3/4

Group 1 aggregates are defined in this standard as: blast-furnace slag, limestone, calcareous gravel, trap rock, burnt clay or shale, cinders containing not more than 25% of combustible material and not more than 5% of volatile material, and other aggregates meeting the Committee's specifications and containing not more than 30% of quartz, chert, flint, and similar materials.

Group 2 aggregates are defined in this standard as: granite, quartzite, siliceous gravel, sandstone, gneiss, cinders containing more than 25%, but not more than 40% of combustible material and not more than 5% of volatile material, and other aggregates meeting the Committee's specifications and containing more than 30% of quartz, chert, flint, and similar materials.

SUPPLEMENTARY DESIGN STANDARDS. Besides the various standards mentioned in the preceding articles, the following references should be particularly noted.

The municipal building codes of New York, Boston, Chicago, and Los Angeles are useful as indicating current practice. The *Uniform Building Code*, adopted by the Pacific Coast Building Officials Conference, and the *Southern Standard Building Code*, prepared by the Southern Building Code Congress in 1946, illustrate a movement to standardize code requirements. The state codes of Wisconsin and Ohio, supplemented by the *Multiple Dwelling Law* of New York State and the *State Housing Act* of California are of interest from the viewpoint of state control.

Much valuable information on structural design will be found in the series of reports entitled *Building Materials and Structures*, sponsored by the U. S. Department of Commerce and published by the National Bureau of Standards. They are obtainable from the Superintendent of Documents, U. S. Government Printing Office, Washington, D. C. The Federal Emergency Administration of Public Works, Housing Division, has sponsored publications applying to particular aspects of building. The standards of the Federal Housing Authority furnish helpful criteria applying to residential work. They are mandatory when mortgages are to be insured by the Authority.

Many trade associations such as the Portland Cement Association, the National Lumber Manufacturers Association, and the Structural Clay Products Institute have made easily available the results of research in their respective fields.

2. DESIGN PROCEDURE

BASIS OF THE STRUCTURAL DESIGN. Prior to the design of a building, an analysis should be made of all mandatory regulations affecting either the architectural or structural work. In the absence of legal requirements, the designer should choose his own standards. These subjects have been discussed in the preceding section.

After conferences with the owners, preliminary sketches and a memorandum specification are developed. These drawings, made to an appropriate scale, should show in plan all office, manufacturing, or storage spaces with elevations or sections indicating clear story heights. They form the bases for the structural design which should be commenced at this stage of the project and thoroughly coordinated with the spatial requirements. For industrial work, the utilitarian demands of the particular industry for which the building is to be used are far more important than artistic considerations.

INFLUENCE OF LOCALITY. All characteristics of the site or geographical location, which may directly or indirectly affect structure, should be studied at this time and reduced to the form of simple notes. Subsurface conditions are most important. Methods of investigation are described briefly in Article 8 of this chapter. In localities subject to earthquakes, the probable severity of seismic disturbance would be noted. In districts where exceedingly strong winds may be expected, the probable wind loads should be compared with the minimums given in Article 1 or required by local building codes.

Owing to the expansion and contraction of building materials caused by temperature variation, joints to provide for such movement are often necessary. Such are particularly important for long concrete buildings erected in the colder climates as mentioned in Article 3. Extreme temperatures obviously require more thorough insulation of the building envelope. Acoustical considerations may, in some cases, influence the foundations and require insulating the structural frame from a source of external vibration.

ECONOMIC CONSIDERATIONS. Even in this preliminary stage of design, the relative prices for various building materials, labor rates, labor efficiency, and union restrictions for the different trades should be recorded. They may have an influence on the choice of materials and structural assemblies. There is also the very important need of checking the availability of materials.

SPECIAL STRUCTURAL REQUIREMENTS. Any special equipment loads, a future horizontal extension of the building or a provision for future, additional stories, should be recorded at this time. The type of foundations should be chosen prior to the actual design of the foundation assemblies, in order to eliminate later changes in column locations. For example, in steel-mill buildings, longer spans would be favored when columns are supported by piles, so as to reduce the number of pile clusters. If there is a probability of unequal settlement, the more rigid types of framing would be inadvisable.

The amount of day lighting or the sort of artificial light demanded by the particular type of industry may have an important effect upon the exterior wall design. If skylights are required, the roof construction is obviously affected.

MECHANICAL AND ELECTRICAL EQUIPMENT. These matters are extremely important for all modern buildings, particularly for factories. The designer should note the requirements which follow:

(1) Requirements for number, size, location, and height of rise for elevators, with particular attention to penthouse dimensions and equipment loads.

(2) General requirements for plumbing with particular attention to the location of soil stacks, standpipes, mains, pumps, water-storage tanks, and sprinkler systems.

(3) If steam is to be produced within the building, requirements of the boiler room and accessories, such as fuel storage. The probable location of steam mains and ducts and their approximate sizes in order to avoid interference with the structural members or other utilities.

(4) Typical lighting demands with particular attention to ceiling outlets as their proper location may influence the framing of the building, and the necessary space required for running the electric conduit often affects the floor design.

(5) For industrial buildings, all specific demands of the manufacturing process, such as special mechanical and electrical equipment or interior clearances, should be identified.

CONCLUSION. When these preliminary investigations have been completed and the structural significance of the subjects mentioned have been reduced to the form of definite design requirements, the choice of the structural assemblies, comprising building frame, floors, roof, walls, and foundations, can be determined. The next six articles describe the more important systems or assemblies employed in this country at the present time with recommendations concerning their appropriate applications. This selection of structural elements constitutes a qualitative design that not only is a vital prerequisite for all quantitative design but will also permit the mechanical engineer to develop the concept of the building to fit the requirements of its particular use, long before the final architectural and structural drawings are completed.

3. PLANNING THE BUILDING FRAME

CHOICE OF THE FRAMING MATERIAL. Structural steel and reinforced concrete, in skeleton construction, are the two normal options for other than comparatively low structures. Bearing-wall designs are seldom economical in this country for buildings more than three stories high. Combined with heavy timber interior framing, they were formerly widely used for factories in "slow-burning" or "mill-construction." Since about 1917, however, such designs have been largely supplanted by structural steel or reinforced concrete. Exterior bearing walls, often combined with interior masonry bearing partitions, are still popular for low residential and commercial structures, but skeleton designs have been found economical for even two-story multifamily housing. Wall-bearing structures usually have an interior framing of structural steel, wood, or lightweight cold-formed steel sections. Reinforced concrete is seldom as appropriate. Complete wood framing is popular for smaller residential and commercial buildings in rural and suburban districts. Structural timber, in the form of trusses, is widely used for industrial work. Timber is also appropriate for rigid frames and arches in buildings as diversified as airplane hangars and auditoriums.

In the general field of building construction, skeleton frames of structural steel or reinforced concrete compete on an economic basis for all buildings up to and including those of moderate height. Above twenty stories, structural steel is the usual choice, and it is often more economical when the height exceeds fifteen stories. Height, however, is not the only consideration. A structural-steel frame can be erected much more rapidly than one of reinforced concrete and is particularly adapted to the one-story industrial building and to the comparatively light floor loads of the multistory city office building or apartment house. On the other hand, the delay in filling an order for structural steel may cancel the advantage of a speedier erection, and either a steel or reinforced-concrete frame may be chosen for the purpose of using a particularly economical type of floor construction, inappropriate for the other material. Such a choice is illustrated by the Master Printers' Building in New York City. This structure is twenty stories high, but the heavy floor loads and the requirement for a comparatively uniform clear story height favored the use of a "flat-slab" (see p. 27-18) concrete design. Because this floor system could not be combined with a structural steel frame, the entire building was constructed of reinforced concrete.

The choice between structural-steel and reinforced-concrete framing may, in some cases, be affected by local building ordinances. An example is the building code of San Francisco which limits reinforced-concrete buildings to a height of 135 ft. The desired architectural treatment of exterior surfaces, as well as the form of structural members dictated by the architectural design, may also play an important part. Structural steel can provide an adequate frame, but if concrete surfaces and forms appropriate to concrete are desired, it is logical to employ concrete for framing purposes.

In the industrial field, structural steel frames are used for textile mills only a few stories high, but for types of industry requiring heavier loads a reinforced-concrete frame with a flat-slab floor system is more economical unless local conditions, or specific design requirements, are unfavorable to concrete. Concrete is particularly appropriate for heavy floor loads, ranging from 150 to 300 lb per sq ft. As the single-story industrial building can be built more cheaply of steel than of concrete, the selection of the framing material often depends on the option between a one-story or a multistory building.

Comparing two alternative designs, both structures have the same gross floor area, 51,000 sq ft. The one-story design has a definite advantage for many types of industry but no valid generalization can be made because each project demands individual study. On the basis of gross floor area, the single-story building generally costs less. There is also a very appreciable saving in the loss between gross area and usable area. The single-story structure is more flexible from the viewpoint of future changes, more easily daylighted, and, except, where gravity systems of distribution can be employed advantageously, is often better suited to manufacturing operations.

On the other hand, a high land value obviously favors a multistory design. The heating load in cold climates and the heat gain in hot climates are also less for multistory buildings. Maintenance of the roof areas again favors this type. Furthermore, in any comparison between steel and concrete framing for the roofs of industrial buildings, the designer should consider the required fire resistance because the cost of fireproofing steel trusses might well be an important factor. This has been one of the reasons for employing concrete rigid frames and shell-roof designs for one-story industrial buildings. They are described in Article 5.

Structural steel framing is the usual choice for pitched roofs supported by either a skeleton design or bearing walls. Steel trusses are employed in building construction for spans varying from 40 to 200 ft. There are many types of steel arches and rigid frames which are suitable for spans up to several hundred feet. All of these wide-span roof assemblies are described in Article 5.

Within recent years, the use of wood as a framing material has come into competition with lightweight steel designs composed usually of cold-formed rather than hot-rolled sections. Complete steel frames of this kind are appropriate for buildings not over three stories high, provided the type of occupancy does not demand heavy floor loads. Where standardization is practicable, the first cost may closely approach that of wood-framed construction with the advantage of using an incombustible material and the elimination of shrinkage. Such designs have proved very economical for machine shops, warehouses, hutments, service buildings, and other single-story structures required for the Armed Forces during World War II. Any kind of exterior or interior finish may be applied over steel with practically the same facility as over wood. Combined with insulated, cellular-steel wall panels, lightweight steel frames are suitable for some types of industrial buildings; with porcelain enameled steel sheets they are used for commercial work. Many of these lightweight steel designs are more or less prefabricated. In most cases the framing members are cut to length in the shop and trusses are shop-welded. For a description of the more or less prefabricated designs suitable for industrial buildings, see p. 27-21.

ARRANGEMENT OF THE FRAMING. The structural design should obviously satisfy the spatial requirements and the demands identified in the preceding sections of this chapter. It is equally important that component parts of the framing should be chosen and combined in a manner to effect economy in field construction as well as in stress analysis. This means that the design should permit simple, direct framing and spans within economical limits except where a prime requirement justifies more expensive construction. It is exemplified by the functional use of appropriate building materials and structural forms.

STRUCTURAL STEEL OR REINFORCED CONCRETE. **Column Locations.** The position of each column, or tier of columns, should be marked on the floor plans. For the multistory building of skeleton design, the best column spacing usually results from dividing the supported area into squares or rectangular areas of approximately equal size. For example, a building 150 ft long and 65 ft wide would suggest a longitudinal spacing of columns at 25 ft and a spacing of about 22 ft across the building. A column spacing of less than 18 or 20 ft is seldom economical. If reinforced-concrete girder framing is used, a maximum span of about 25 ft, and for rolled-steel girders a maximum of about 40 ft, is desirable. This limit for concrete may be extended to about 40 ft, but it would generally be uneconomical. The heaviest of the standard wide-flange steel girders, 36 in. deep, may occasionally be used to advantage on spans up to as much as 60 ft.

Exterior steel columns are placed a clear distance of 5 or 9 in. back from the building line. The larger dimension allows sufficient depth to accommodate 8-in. bond stones or a nominal 4-in. thickness of stone facing with one course of brick backing. Exterior reinforced-concrete columns, if covered by masonry or other architectural surfacing, are set back the distance that the surface treatment requires. Where not so covered, their outer surfaces may coincide with the building line as the reinforcement is adequately protected by the required concrete fireproofing.

In wall-bearing construction, the location of interior columns follows the same principles, except that masonry partitions may serve as bearing partitions, or as interior bearing walls, when their position is such as to provide support along lines that divide the floor area into spans suitable for the floor system. Bearing partitions, or bearing walls, should be shown upon the structural floor plans.

Column Types. Structural steel columns are usually of standard H section. Other types, e.g., pipe, and angle, are occasionally employed to meet special conditions. Cover plates are often used to increase the thickness of the flanges for heavily loaded columns. When sizes are computed and weights of structural steel columns are estimated, it should be remembered that fireproofing is an essential for all fire-resistant construction.

The flexibility of reinforced concrete permits changing the concrete section, the concrete mixture, and the steel reinforcement at any floor level. Standardization of the form work by avoiding all changes not absolutely justified by a reduction in material quantities, or other economic advantage, is a basic principle of concrete design. On the other hand, oversized columns waste floor area and those of minimum size, requiring maximum percentages of reinforcement, are often uneconomical. The form material should also be considered. Sheet-steel cylinders, commonly used to form round columns, so widely employed for industrial plants, are easily altered to suit varying column dimensions whereas a change in a wood form may require a round trip to the job form-building shop.

Reinforced concrete columns may be of practically any cross section provided design requirements are met. The only other restrictions are the practicability of constructing, filling, and stripping the forms and the appropriateness of the column section to receive the beams, girders, or other structural elements which they support. The common sections are square, oblong, round, oval, or as shown in Fig. 1. The types of columns ap-

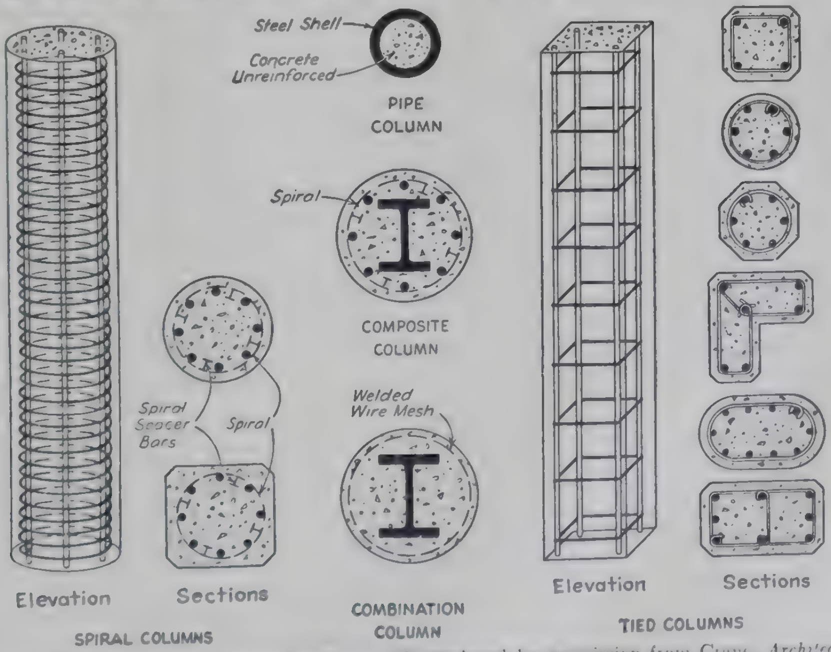

FIG. 1 Reinforced-concrete column sections. (Reproduced by permission from Crane, *Architectural Construction*, John Wiley and Sons, 1947)

propriate for reinforced-concrete designs are described in the following paragraphs based on the classification given in the *Report of the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete* (Ref. 3).

(1) *The tied column* is reinforced with longitudinal bars or rods and separate lateral steel ties. This is the simplest design and widely used but, as its carrying capacity for a given cross section is less than any of the following designs, it would be discarded in favor of another type when the required size became too large for either economy or appearance.

(2) *The spirally reinforced column* is reinforced with longitudinal bars or rods enclosed by a closely spaced steel spiral. This design is particularly applicable to heavily loaded buildings such as factories, warehouses, and garages. In such structures a tied column is often appropriate for the top story, below which the spiraled design would be used.

(3) *The composite column* consists of a structural steel, or cast-iron section, encased in concrete reinforced with both longitudinal and spiral steel. A hollow-metal core can be used if filled with concrete. Loads are transferred to the metal core by bearing members such as billets, brackets, or other positive connections; they are placed at the top of the metal core and at intermediate floor levels where required. This design permits a much smaller cross section for any given load than even the spiraled column. Structural steel H sections are the usual choice for the column cores. They can be economically erected in one piece through a height of about six normal stories and are often helpful in reducing the size of heavily loaded columns through the lower stories of a comparatively high concrete-framed building.

(4) *The combination column* is a structural steel section encased in concrete 2 1/2 in. thick over all metal (except rivet heads), reinforced with a welded-wire mesh. Special brackets are used to receive the entire floor load at each floor level. This design has the same application as the composite column but is not as widely used.

(5) *The pipe column* is a steel pipe section filled with concrete. This type is similar to the Lally column. Its particular application is in low buildings and where fire-resistive standards are not severe. Often it may take the place of the interior wood column in wall-bearing construction and serve as a support for the lighter types of structural work.

Beam and Girder Locations. The designer should first decide between a "short-span" or a "long-span" system for the floor construction. The term short-span identifies a group of structural floor designs that are used on spans varying from about 6 to 10 ft and consequently require one or more intermediate beams between each line of columns.

Long-span floor systems are those capable of spanning, under various loads within the usual range, from 20 to about 30 ft, thus eliminating the need for intermediate beams. As the decision between these two different types of floor construction affects the design of the framing, it should be made at this time, prior to the choice of the particular type of floor system.

Long-span designs are particularly suitable for light and medium floor loads where there are no heavy concentrations. Avoiding beams except along column axes, particularly where columns and connecting beams can be concealed by partitions, improves the general appearance of a room and facilitates ceiling lighting. To obtain a flat ceiling with a short-span design, by the use of a hung ceiling, is usually more expensive than to choose a long-span design, but there may be structural reasons which favor the shorter slab spans.

The direction in which to run the girders or deeper beams may be decided by any one of several factors. If windows are to extend as high as possible, girders should run across the building, permitting spandrel beams of lesser depth. This arrangement also favors structural rigidity, particularly desirable for high, narrow buildings. Another consideration is the desirability of placing the girders, or heavier beams, on the shorter spans for the sake of conserving headroom or improving the appearance of an open floor area. The designer will usually find that the special conditions of his particular building result in a definite preference.

In structural steel design, the beams and girders may be framed with their top surfaces flush, as shown in Fig. 2, or the beams may be dropped sufficiently to avoid the expense of coping their upper flanges, as shown in Fig. 3. If precast-concrete slabs, gypsum plank, or similar units are used as a structural floor or roof deck, a flush surface is required. The same is usually preferable for long-span designs as the principal beams frame into the columns and are not supported by girders. Either type of assembly may be preferable for short-span designs with poured concrete slabs. If panels are square or nearly square, the girders determine the clear story height, and it may be advantageous to drop the beams.

Flat roofs, identified as those that are horizontal, or only slightly sloped in one or more directions for the purpose of drainage, are usually framed with the same materials and often with the same arrangement of framing members as used for the floors below. For multistory factories, the same system should usually be retained unless special features of the roof, or obvious economy, justifies a change. Pitched roofs are framed of steel or wood because of the difficulty of pouring concrete on steep slopes. The various designs that have been developed for precast-concrete framing have not, up to the present time, been very widely used.

Beam and Girder Types. A variety of structural steel shapes and built-up sections have been used for framing buildings. Present practice favors the wide-flange H sections for the principal beams and girders, unless the span or load requirements demand built-up units such as plate girders or trusses. Around openings, such as stair wells, the steel section is chosen to facilitate the stair erection, and various lightweight types have been developed for roof construction. Typical stair arrangements are shown in Fig. 4.

FIG. 4. Steel stair designs. (Courtesy of the National Association of Ornamental Metal Manufacturers)

The usual reinforced-concrete beam or girder is of T section, the flange of the T being supplied by the contiguous floor construction which is placed monolithically with the beam or girder. Around openings, such as stair wells, the section takes the form of an inverted L. In the case of an exterior beam spanning between wall columns, along an open well, the section becomes rectangular. Figure 5 shows the usual sections, including shallow beams, which have the advantage of facilitating ceiling installations but require more reinforcement because of their reduced effective depth.

Concrete Flat-slabs Designed with Specified Moment Coefficients. For multistory factories this system often offers more advantages than beam-and-slab or beam-and-girder construction. There are obvious exceptions where many openings, changes in floor level, concentrated loads, offset columns, or other structural variations interrupt continuity between adjacent panels. Furthermore, in some cases, beams or girders may be helpful in resisting lateral forces.

The conventional flat-slab assembly is shown in Fig. 6. It is particularly suitable for heavy floor loads. If columns can be placed without reference to interior requirements, a spacing of about 20 to 22 ft is economical for superimposed floor loads up to 300 lb per sq ft. Garages are often designed with a column spacing of about 26 by 22 ft. A 30-ft spacing approaches the practicable maximum for a uniformly distributed superimposed load of 200 lb per sq ft, unless the dead load of the construction is decreased by fillers or voids. In Fig. 6, wide, shallow sections of the same depth as the drop panels are used along all discontinuous edges of the slab. Narrower and deeper beams are often desirable around stair and elevator wells above partitions. Openings of any size may be cut through a flat slab if adequate structural provision is made for the stress requirements.

FIG. 5. Types of reinforced-concrete beams and framing plans. (Reproduced by permission from Crane, *op. cit.*)

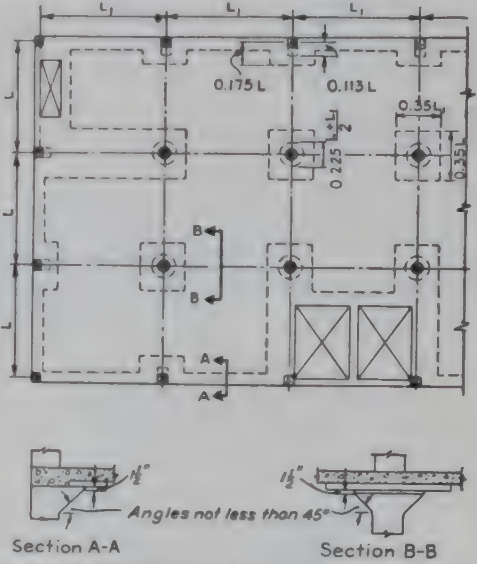

FIG. 6. Typical reinforced-concrete flat-slab design. (Reproduced by permission from Crane, *op. cit.*)

The designs employing specified moment coefficients, such as are given in the *Building Regulations for Reinforced Concrete of the American Concrete Institute*, are limited in their application. The ratio of length to width of panels must not exceed 1.33; there must be at least three continuous panels in each direction. Successive span lengths in each direction must not differ by more than 20% of the shorter span.* Interior columns have flared capitals; brackets are used for exterior columns. Drop panels, as shown, are usually placed over columns as they are structurally economical but can be omitted if the slab is made thick enough to satisfy stress requirements. When drop panels are used over interior columns, half drops are used over exterior columns. Interior columns are usually of circular cross section with capitals in the form of an inverted frustum of a cone. Exterior columns are usually square or rectangular, windows often extending from column to column and the spacing chosen to fit stock sash, or the dimensions of other materials. Spandrel beams may be placed either above or below the slab with which they are cast monolithically. They may be comparatively wide and shallow or of any adequate section to suit the exterior wall construction.

Concrete Flat Slabs Designed by Elastic Analysis. For structures having less than three consecutive panels in each direction, or where the size or shape of panels does not fall within the specified limits, or where the designer desires to eliminate column capitals, specified moment coefficients are inapplicable. An appropriate procedure, implementing the method of elastic analysis, is given in *Building Regulations for Reinforced Concrete of the American Concrete Institute*, 1947. It should be noted that the use of specified moment coefficients for flat-slab designs which meet the requirements mentioned above is merely a special case for which it is possible, within these limits, to use a definite moment distribution and greatly simplify the computations. This practice corresponds to the use of specified moment coefficients in the design of a series of continuous concrete beams or girders, having spans of approximately the same length.

---

* This is the requirement of the American Concrete Institute. The *Report of the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete*, 1940, allows only 15% variation.

The broader application of continuity in concrete design has been widely accepted during recent years, as illustrated by the omission of column capitals and the use of flat slabs having a uniform thickness, or combined with "slab bands." Designs of this type are particularly appropriate for the comparatively light loads and moderate spans of apartment houses but have also been used for industrial buildings. Any such system, comprising a solid concrete slab, provides facility for embedment of electric conduit or other pipes, and the smooth surfaces of floor and ceiling can be utilized to save expense on fill or finishes.

Expansion or Contraction Joints. All commonly used building materials expand or contract as their temperature is increased or lowered. In the case of masonry assemblies, the resulting deformations, except under very extreme exposures, are more or less uniformly distributed throughout the joints and seldom require special provision. Structural-steel frames, used in building construction, do not usually require special provision for expansion or contraction joints except in the case of roof trusses of considerable length, as mentioned in Article 5. In reinforced-concrete design, however, joining is required for many types of structures. The following paragraphs on this subject are quoted from the *Report of the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete.*

> **Purpose and Location.** *(a)* If a reinforced-concrete structure is free to expand and contract with variations in temperature or moisture conditions (uniform over the section), no stresses of any importance will be developed. When the movement of the structure is restrained, however, or when temperature or moisture variations are not uniform over the section, stresses are introduced which should be provided for in the design.
>
> *(b)* Points requiring special consideration are located where large changes in cross section occur or at corners in long members where expansions or contractions may result in rupture of the side members. No amount of reinforcement will prevent the formation of cracks in a restrained structure in which the required change in length exceeds the extensibility of the concrete, but reinforcement properly designed will serve to distribute the cracks.
>
> *(c)* Joints providing a complete separation in the structure, when properly located, can relieve the restraint and prevent or greatly minimize the development of cracks. Such joints should be carefully designed with respect to the type of structure and should provide for the full expected movements without introducing local stresses severe enough to rupture the concrete. They should be located at predetermined points and fully detailed on the drawings. They may or may not be designed to carry load or distribute stress across the joint. Frequently this type of joint requires some form of protection to keep out extraneous material.
>
> **Expansion Joints in Long Buildings.** *(a)* Expansion joints are expensive and in some cases difficult to maintain. They are, therefore, to be avoided if possible. In relatively short buildings, expansion and contraction can be provided for by additional reinforcement. No arbitrary spacing for joints in long buildings can be generally applicable. In heated buildings joints can be spaced farther apart than in unheated buildings. Also, where the outside walls are of brick or of stone ashlar backed with brick, or where otherwise insulated, the joints can be farther apart than with exterior walls of lower insulating value.
>
> *(b)* In localities with large temperature ranges, the spacing of joints for the most severe conditions of exposure (uninsulated walls and unheated buildings) should not exceed 200 ft. Under favorable conditions buildings 400 to 500 ft long have been built without joints even in localities with large temperature ranges.
>
> *(c)* In localities with small temperature ranges, the spacing of joints for unheated buildings or with uninsulated walls should not exceed 300 ft. In such localities buildings up to 700 ft long have been successfully built without joints where other conditions were favorable.
>
> *(d)* In roof construction, provision for expansion is an important factor. The joints in the roof may be required at more frequent intervals than in the other portions of the building because of more severe exposure. In some cases expansion joints spaced 100 ft apart have been provided in roofs and not in walls or floors.*
>
> *(e)* Joints should be located at junctions in L-, T-, or U-shaped buildings and at points where the building is weakened by large openings in the floor construction, such as at light wells, stairs, or elevators. Joints should provide for a complete separation from the top of the footings to the roof, preferably by separate columns and girders.

---

* In regard to paragraph *(d)*, it is the author's opinion that if a joint across a roof slab is expected to function, the slab should not be rigidly connected to the supporting structure, unless corresponding joints are provided in the latter.

Joints of this type provide for contraction or expansion of the concrete by an actual separation of structural members and should not be confused with "construction joints" which are merely horizontal or vertical planes along which it is necessary to interrupt the continuous placing of concrete as the work progresses from day to day.

Control Joints. These are a modification of the expansion or contraction joint which produce a "weakened plane" through a concrete section for the purpose of controlling the location of potential cracks due to shrinkage occurring either during the early stages of hydration or subsequently by reason of drying or chilling. Such should be seriously considered where a change in the concrete cross section, or extensive unbroken areas of walls or floors, present the probability of developing secondary stresses due to volumetric change. Other critical locations are where wall panels join pilasters, where steel columns are cast into concrete walls, and where openings occur adjacent to long or thick wall sections.

WOOD FRAMING AND PREFABRICATION. Masonry Bearing Walls with Interior Wood Framing. This type of construction is often identified in building codes as "Ordinary Construction." Interior bearing walls are frequently used, particularly in basements and cellars. Steel or iron columns and structural steel girders are occasionally combined with wood-joist floor construction and wood-framed roofs. Most building codes have specific regulations applying to the manner in which structural members are assembled and supported.

If wood posts are used in the basement they should rest upon cast-iron bases for protection against moisture. Pipe columns are also supported upon cast-iron or steel-plate bases, they are generally preferable to wood posts. Any type of post or column, bearing wall or bearing partition, should rest upon concrete footings rather than merely upon a concrete cellar floor unless the latter is laid directly over rock. The lighter structural-steel sections are appropriate for girders supporting wood-joist floors and are greatly preferable to wood girders as an aid in diminishing differential settlement between the interior and exterior of the building. In this connection it should be noted that when exterior masonry bearing walls are used with interior wood framing there is the obvious tendency for the shrinkage of the wood to cause settlement of the interior assembly. Timber shrinks only slightly in direction parallel to the grain, but the cross-grain shrinkage may be considerable. For this reason, the framing should be arranged to eliminate such effects as far as practicable. The studs of wood-bearing partitions should rest directly upon the plate below when supported by a partition and directly upon the wood girder where such is used. If carried by a steel girder, this is also desirable unless a sole plate is considered necessary to permit nailing the lower ends of the studs.

Wood girders supported by a masonry wall are usually either held in place by a metal wall hanger or built into a recess of the wall and supported by a metal plate. The recess is made large enough to provide ventilation against dry rot. Wood joists should have a 4-in. bearing on exterior walls and should be secured by metal anchors placed on at least one joist in every 6 ft. The ends of joists are also beveled to permit release in case of fire without dislodging the masonry. Where supported by interior masonry walls, joists in small dwelling-house construction are merely lapped across the wall and spiked together, but special methods of support may be required for larger structures. Where supported by wood partitions which, in two-story dwellings, would normally require 2 by 4-in. studs, the floor joists are similarly lapped across the partition plate and spiked. Solid bridging is used at midheight of all wood-stud partitions. Where lateral stiffness is essential, partition bridging is inclined. Studs are doubled at sides of openings, with wood lintels or trusses across the heads.

Typical floor construction is of wood joists, usually 2 by 10 in. or 2 by 12 in., nominal sizes, spaced 12 to 16 in. on centers. A 3-in. minimum nominal thickness may be demanded by a municipal code within fire limits. Bridging is placed at a maximum spacing of 8 ft. The subflooring may be of $^7/_8$-in. matched boards, laid diagonally over the wood joists, or of plywood. Metal lath, occasionally wood lath, or gypsum lath serve as a base for plaster. Well-nailed metal lath, lapped and wired where sheets intersect, affords the best insurance against plaster cracks. Gypsum lath, often called "rock lath," requires less plaster and gives slightly better heat insulation. Many types of fiber and composition boards, finished to present a suitable ceiling surface or adapted to the application of paint, are available. If the roof surface is comparatively flat, construction is similar to that of the floors. If pitched, the rafters and ridge, forming the skeleton-like frame, carry shingle lath, solid boarding, or other desired material serving as a base for the roof surface and providing rigidity for the entire roof assembly. Where attic spaces are heated, an appropriate type of insulation is used between the roof rafters instead of in the attic floor.

Heavy Timber or Mill Construction. This term identifies buildings with exterior masonry walls and in which the interior structural framing is of heavy timbers designed to resist the effect of fire. For this reason it is sometimes called "slow-burning construction." Interior bearing walls of masonry are often used, particularly in structures of large area, for which they may be designed as fire walls. Wood posts are generally connected by steel or iron caps, pintles, and base plates, or by timber splice blocks of special design. Columns are not permitted to rest on floor timbers, and either stone, cast-iron, or steel bases are used to transmit the load to masonry foundations. Where beams or girders rest on masonry walls, boxes of self-releasing type, or an appropriate hanger, are required. Most building codes give specific regulations for connections between beams or girders and the supported columns or walls, and for the support of beams carried by girders.

In typical mill construction, wood girders span from an exterior wall to an interior column and then from column to column in one direction only. The girder spans between columns vary from 12 to 18 ft. No beams are used at right angles to the girders. The distance between the girders, varying from 7 to 10 ft, is spanned by heavy plank flooring. The smooth under surface of the floor plank lessens the flammability of the construction. Lath and plaster are not used on typical designs. Wood columns are of a minimum 8-in. nominal thickness in any dimension; corners are rounded or chamfered. Occasionally steel or cast-iron columns are used; they are generally permitted for this classification by building codes if protected to furnish a 1-hr fire-resistance rating. Wood beams and girders supporting floors have a minimum nominal thickness of 6 in. and a minimum nominal depth of 10 in., irrespective of stress requirements. Floors are usually composed of wood plank, tongued and grooved or preferably splined, not less than 3-in. nominal thickness and laid across the timber framing. Planks set on edge and spiked together are also used to form a laminated floor; the minimum nominal thickness of this design is 4 in. Over the structural wood floor, a 1-in. finished wood floor is laid to take wear and improve the appearance.

As the complete wood-framed structure, so widely used in this country for dwellings and small, commercial buildings, erected in rural districts, has practically no application for industrial buildings, the subject is omitted in this book.

Prefabrication. In the building industry this term identifies a degree of factory assembly beyond that customary in conventional practice. Several of the wall designs shown in Article 7 are types of shop-fabricated units similar in principle to those used in prefabricated structures. Many of the newer designs in laminated wood, used for both beams and trusses, are characteristic of present-day trends which gain economy by shop manufacture. Prefabrication is consequently a relative rather than specific designation, implying merely a method of construction by which economy is gained through the standardized, high-mechanized shop manufacture of building elements, such as wall, floor, and roof panels. Up to the present time the more complete types of prefabrication have been largely confined to single-family dwellings, military hospitals, barracks, and small service structures.

These designs are usually of steel or wood-panel construction. Although there have been many fairly complete prefabricated concrete systems patented during the last generation, most of them were dropped after the construction of a few test houses. Others have been applied, more or less successfully, over a period of years, but have little significance for industrial work. Precast structural members of reinforced concrete have, however, interesting possibilities for factories and warehouses. During World War II precast concrete columns, girders, and slabs were erected, and two large single-story warehouses were built for the Navy of thin-shell precast concrete. The framing comprises a system of bents supporting precast roof panels. These bents are of hollow section, and reinforcement is welded to obtain continuity where adjacent segments join. For a detailed description of these buildings see Refs. 4 and 5. In 1947 four dormitories were erected for the University of Vermont, at Burlington, Vt., using precast concrete slabs 8 in. thick for the structural portion of the exterior walls and precast concrete slabs 6 in. thick for the interior partitions. These elements supported concrete floors and roofs which were poured-in-place. The complete exterior wall section comprised a 4-in. exterior surface of brick, a 2-in. air space, and the 8 in. of precast concrete slab. No plaster was applied to the interior surfaces of either walls or partitions. Although these uses of precast concrete slabs were for residential work, systems of this type have particular significance for warehouses and garages. The following year eight large dormitories of a similar design were erected for the University of Connecticut, at Storrs, Conn.

In another noteworthy design the exterior walls are composed of Latisteel sections with 2 in. of concrete. Panels are cast in a horizontal position. After a 24-hr curing period, they are erected by crane and bolted in place. The roof is of conventional design, having a steel deck of welded sections supported by steel trusses. It is surfaced with insulation and waterproofing. This system has particular application to industrial work.

4. CHOOSING THE FLOOR CONSTRUCTION

Structural floor systems can be divided into two groups, the long-span and the short-span designs. A choice between these two types should be made, as mentioned in Article 3, prior to the planning of the building frame. The selection of a particular design for the structural floor follows logically as the next step in determining the structural assembly for a building. In this book *system* identifies the structural assembly spanning between supports, such as beams or girders, or bearing walls. The following paragraphs describe the more popular types of floor construction and indicate the particular application of each type to conditions which will be known by the designer at this stage of his work. The maximum spans and limiting dimensions noted for the various designs conform to structural standards generally accepted, but they should be checked against the requirements of local building codes.

The term *long span* identifies designs which ordinarily require no beams except along the center lines of columns. As a group, they are particularly suited to light and medium, uniformly distributed superimposed loads, 40 to 100 lb per sq ft, and to spans 15 to 30 ft. They have a wide application except for the heavier industrial loads. The *short-span* designs require structural supports, usually in the form of beams, spaced 6 to 10 ft apart. These designs are used for all types of occupancy.

LONG-SPAN DESIGNS. Metal-pan System. This is one of the most popular of the reinforced-concrete ribbed designs. A comparatively thin, lightly reinforced-concrete slab, normally 2 to 3 in. thick, is poured over voids formed by steel forms as shown in Fig. 7. This slab, called the "topping," is supported by and cast monolithically with reinforced-concrete ribs, or joists, spaced 12 to 30 in. apart, face to face. Supplemented by the slab, these ribs form a series of T beams, spanning between the principal framing members of the floor assembly and furnishing the structural support for the system. The width of the ribs is normally 5 in. They should be straight and of a depth not over three times their average width. The slab thickness should be at least one-twelfth of the clear distance between ribs. Reinforced-concrete bridging, usually 4 in. wide and of the same depth as the ribs, is required on long spans. The width of ribs supporting masonry partitions is increased as required to carry the additional load. Rigid, electric conduit is sometimes placed in the open spaces beneath the pans, or the thickness of the topping is increased to accommodate such installations. In many cases a fill, about 3 in. deep, is placed over the structural floor. This provides space for the conduit or other pipes.

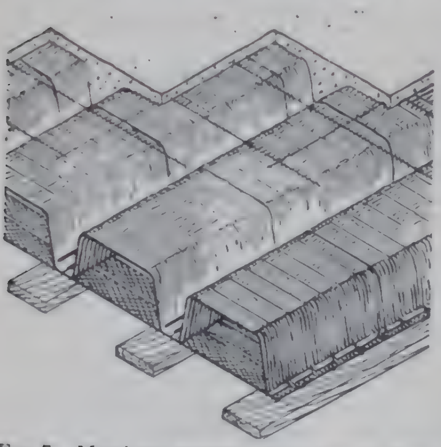

FIG. 7. Metal-pan system. (Courtesy of Truscon Steel Co.)

Metal pans are manufactured in standard widths of 20 and 30 in.; the latter is a generally accepted maximum. Smaller widths are available for filling odd spaces. Standard depths vary from 6 to 14 in. by 2-in. increments. Metal pans are assembled by lapping the ends. Appropriate lengths are supplied by manufacturers to suit any length of floor panel. The end units are furnished with tapered sides or with both side and top tapered, so as to enlarge the cross section of the concrete rib, or of both rib and slab, adjacent to supports. This system can be used with either steel or reinforced-concrete framing or with bearing walls. For additional information on this subject, refer to the Concrete-reinforcing Steel Institute.*

Structural Clay Tile System. This design, shown in Fig. 8, is similar to the metal-pan system except that structural clay-tile fillers are used in place of pans. The tile may be 12 by 12 in., with depths varying from 3 to 12 in.; 12 by 16 in., or 16 by 16 in., with depths from 3 to 10 in. A 12- by 20-in. tile is also manufactured with depths varying from 4 to 10 in. The larger sizes of tile usually furnish the more economical design. Oblong tile are assembled with the longer dimensions perpendicular to the ribs. As a 5-in. rib would normally be used with a 16-in. tile, the center-to-center spacing of the ribs is 21 in.

---

* Wood or plywood forms are occasionally employed for the same purpose, but metal is generally more economical. Except for the material used to enclose the void between ribs and details in regard to the forming, all characteristics are identical.

A 6-in. width of rib is appropriate for a 20-in. tile, resulting in a 26-in. center-to-center spacing. A $1\frac{1}{2}$-in. minimum thickness of concrete topping is generally required for the 12- by 12-in. tile and a 2-in. minimum thickness for the larger sizes.

The lower faces of the tile provide an excellent surface for plaster. Soffit blocks of the same material are often used, as shown in Fig. 8. This practice is recommended. The ends of each line of tile, where in contact with the concrete, are generally closed by sheets of metal or other appropriate means. Bridging is not required because of the lateral support furnished by the tile. The thickness of ribs is increased beneath partitions as noted for the metal-pan system. Rigid electrical conduit is generally placed in the concrete slab over the tile or in a fill laid over the structural floor. This system can be used with steel or reinforced concrete framing or with bearing walls.

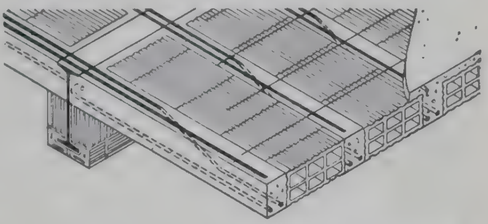

FIG. 8. Standard clay-tile system. (Courtesy of National Fireproofing Co.)

Concrete-block Systems. The essential characteristics of these designs are similar to clay-tile construction except that the fillers between the reinforced-concrete ribs are hollow block composed of portland cement combined with sand, cinders, slag, Haydite, Waylite, Super-Rock, or other lightweight aggregate. Haydite is composed of burned shale ground to the required size; Waylite and Super-Rock are made from expanded blast-furnace slag. Although these materials are produced in many parts of the United States, their availability at a competitive price should be checked for any particular locality. Figure 9 shows a typical design, and Fig. 10 a variation of the standard concrete-block system which provides a uniform surface for plastering without the use of soffit blocks. These systems can be used with steel or reinforced-concrete framing or with bearing walls.

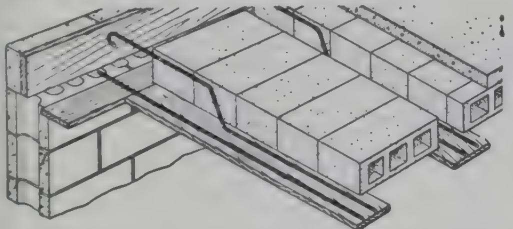

FIG. 9. Standard concrete-block system. (Courtesy of Portland Cement Assoc.)

Various other types of filler blocks, such as gypsum and compressed fiber units, are less frequently used and have little application to industrial buildings.

Two-way Systems. If the framing of a floor assembly results in panels that are square, or approximately square, it may be economical to use any one of the concrete-ribbed systems in a two-way design. This results in forming a type of flat plate which requires a supporting beam, or bearing wall, on each of the four sides of the panel. The particular application of such designs is for buildings which require a number of large, square, or approximately square panels, 20 to 25 ft between column center lines, and preferably for floor areas large enough to permit several continuous panels of about the same size in each direction. Two-way designs are similar to the corresponding one-way systems except that the metal-pan or filler block must present a solid surface on all four sides, or one which will at least prevent the entrance of any appreciable amount of concrete into the interior of the void or block.

In the metal-pan system, this requirement is met by the use of steel domes identified as the "Grid System." The Grid System steel domes have their particular application for industrial buildings. Domes are available in an 8-in. depth, 19 by 19 in., and in a 4-in. depth, 18 by 18 in. The width of the rib is controlled by the flange width of the dome; it is 5 in. for the deeper type and 4 in. for the shallower. The 8-in. depth, with 6 in. of concrete topping over the metal, has been used on panels 36 by 38 ft to support a uniformly distributed superimposed load of 125 lb per sq ft. The 4-in. depth has been used on 20 by 20 ft panels with a 2-in. concrete topping for a similar load of 100 lb.

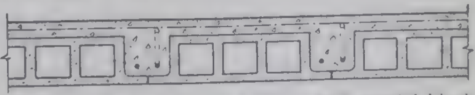

FIG. 10. Concrete-block system, with special block forming soffits of concrete ribs. (Courtesy of Portland Cement Assoc.)

The clay-tile system may also be used in a two-way design. Closures are generally placed across the open ends of the tile to eliminate the entrance of concrete into the cells. Specially designed tile, however, are available for two-way systems, such as the gypsum unit, manufactured with four solid faces, but they have little application to industrial buildings.

Precast Concrete Joist Construction. The joists may be cast of stone, cinder, Haydite, or other lightweight-aggregate concrete. They are manufactured in standard depths of 6 to 14 in., varying by 2-in. increments. Special joists are available up to 22 in. in depth with flanges up to 16 in. wide. These precast concrete joists are particularly appropriate for wall-bearing designs and comparatively low buildings. They may be used with either steel or reinforced-concrete framing. Although identified ordinarily with light loads and comparatively long spans, they may also be found satisfactory for commercial buildings and warehouses, as the deeper designs can support comparatively heavy loads on spans up to 30 ft. Bridging in the form of a concrete rib, cast-in-place, is used on spans over 16 ft for the 8-in. joist and on longer spans for the deeper units. Joists are usually placed 2 to 5 ft apart, carrying precast concrete slabs 2 to 3 in. thick, or cast-in-place concrete slabs having a minimum thickness of 2 $^1/_2$ in. Concrete plank are often appropriate. Plank are attached by clips to anchors cast in the joists. They can be sawed, nailed, or drilled. A 2 $^3/_4$-in. thickness might be used on a joist spacing of 5 ft for light and medium floor loads. The particular economy of this system occurs where it is permissible to leave the joists exposed on the underside of the floor.

Precast Concrete Cored Designs. The Flexicore precast system comprises structural units 12 in. or more in width and of a length and depth required for the particular span and load. These units are available in many localities and can be assembled with bearing walls, steel or reinforced-concrete framing. Round cores are obtained by expanding elastic tubes to form the inner void around which stone, gravel, or lightweight-aggregate concrete is poured in steel molds. With adequate steel reinforcement, prestressed in shop manufacture, a 6-in. total depth can be used to support light loads on spans up to about 22 ft. For short-span designs, up to 10 ft, superimposed loads of several hundred pounds per square foot may be supported. Because of the slight variations in top surfaces, characteristic of all such unit construction, a mortar topping about $^1/_2$ in. thick should be applied as a base for linoleum, asphalt tile, or similar surface finishes. Ceiling surfaces are reasonably smooth, and electric conduit can be run within the structural thickness of the slab. These units are particularly appropriate for low residential and commercial structures. They are used with steel framing or supported by bearing walls.

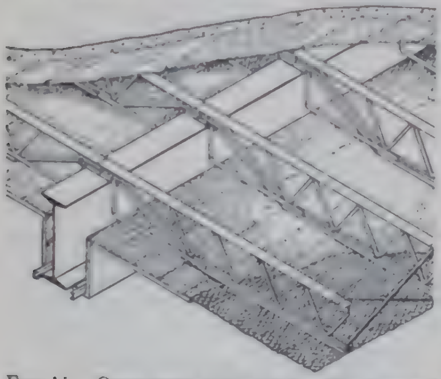

FIG. 11. Open-truss steel joists. (Courtesy of Truscon Steel Co.)

Open-truss Steel-joist Construction. The system shown in Fig. 11 is particularly adapted to buildings with comparatively light floor loads, and although occasionally used for high structures is more appropriate for low buildings. It competes in the same field as the precast-concrete joist assembly but is not recommended for use with a reinforced-concrete frame. Although inappropriate for heavy industrial loads and as a support for machinery which might induce vibration, open-truss steel joists might well find their place in the more lightly loaded buildings of an industrial group. The spacing of joists is limited to 24 in. for floors, 30 in. for roofs having a poured concrete slab, and 7 ft for roofs having a steel or wood deck. The structural slab, supported by the joists, is usually of concrete 2 to 2 $^1/_2$ in. thick, poured in place over ribbed-wire fabric of close mesh or welded-wire fabric backed by heavy paper. Joists are supplied in depths varying from 8 to 16 in. by 2-in. increments. Steel bridging, in the form of rods or fabricated from $^3/_4$-in. channels, is placed at a maximum spacing of 7 ft. A 16-in. joist supporting a 2 $^1/_2$-in. concrete slab, can carry a uniformly distributed superimposed load of 75 lb on spans up to 30 ft with a joist spacing of 21 in. This system is used with steel framing or supported by bearing walls. For further information on this subject refer to the *Steel Joist Institute Specification*.

Stran-steel Joists. These lightweight, cold-formed steel sections are used as floor joists for the lighter load requirements and moderate spans. They are manufactured of 16 to 11 gage copper-bearing steel and in depths of 6 to 9 in. A typical assembly comprises a 2-in. reinforced-concrete slab, supported by corrugated metal laid over the joists, which are usually spaced 12 to 32 in. on centers. With a spacing of 18 in., a 9-in., 13-gage joist, with a 2-in. concrete slab, can support a uniformly distributed load of approximately 60 lb per sq ft on an 18-ft span. Twenty feet is about the limit for light loads. These joists have their particular application for low residential buildings. They would seldom be appropriate for the requirements of even light manufacturing, but might be an economical choice for floors of an industrial housing development. They are used with steel framing or bearing walls.

Concrete Flat Slabs. These designs, particularly appropriate for industrial buildings, were discussed in Article 3. They are types of construction rather than floor systems.

SHORT-SPAN DESIGNS. Solid Reinforced-concrete Slabs. In combination with steel framing, either stone or lightweight aggregate may be used. With reinforced-concrete framing, stone-concrete slabs represent a standard design. However, it is not practicable to use a lightweight aggregate with concrete framing except in the rather unusual case where the supporting structural members, as well as the floor slabs, are cast of the same material. This has occasionally been done, however, where a prime requirement was to lighten the dead load of the entire assembly. Concrete slabs used as structural floors normally have a minimum thickness of 4 in.; a 3 $^1/_2$-in. thickness is permitted for roofs. Figure 12 shows a typical section with structural-steel framing which would appear the same for either stone or lightweight aggregate.

Soffit Reinforcement to Retain Fireproofing

FIG. 12. Short-span, reinforced-concrete slabs supported by structural-steel framing. (Reproduced by permission from Crane, *op. cit.*)

In short-span assemblies of this type, the beams may be connected to the girders so that the top surfaces of the two are at the same level, or the beams may be dropped sufficiently to avoid coping their upper flanges. In such designs, the structural-concrete slab is often finished flush with the upper surface of the structural steel, but it is better practice to provide a minimum thickness of 1 in. of concrete over the upper flanges. This concrete serves as a protection for the welded-wire reinforcement of the slabs where it passes over the beams and permits the introduction of a 4-ft width of the same steel mesh along the girders, placed with the heavier wires at right angles to the girder flanges. The purpose of this additional reinforcement (shown in Fig. 2) is to minimize the probability of cracks developing parallel with the sides of the girders.

The so-called cinder-concrete arch, actually a short-span slab, as shown in Fig. 12, has been a standard type of construction in New York City for many years. The more general use of this design is limited to clear spans between steel beams of not over 8 ft. The reinforcement, in the form of welded-wire mesh, draped over the supporting steel beams, is designed for the span and loading conditions. Haydite, Waylite, and various lightweight cement-aggregate mixtures, such as Aerocrete, Porete, and Gritcrete, are also used for both short-span floor and roof slabs.

Precast cement-aggregate slabs are occasionally appropriate for short-span floor systems supported by structural-steel framing, especially where it is unnecessary to fireproof the steel, but their special application is for roofs. Slabs are cast of small-size stone aggregate, Haydite or other lightweight material, and reinforced with galvanized, welded-steel mesh. They are anchored to the girders by bolts. Such systems have been used successfully for many types of occupancy varying from industrial buildings to schools. When lightly reinforced, a web thickness of 2 $^1/_4$ in. with channels 4 $^3/_4$ in. deep is suitable for a uniformly distributed superimposed load of 75 lb per sq ft on spans up to about 10 ft. Considerably heavier loads can be carried by increasing the amount of reinforcement. The channel sections rest upon either steel or concrete beams to which they may be bolted if required. Joints are grouted with cement mortar and troweled level. A $^1/_2$-in. mortar surfacing is applied beneath linoleum or asphalt tile. If wood floors are required, metal clips are inserted in the grout between the slabs for the retention of wood sleepers.

Lightweight concrete is also employed in the form of precast channel sections and plank. The former are appropriate for light or medium, uniformly distributed floor loads on spans up to about 8 ft; the 2-in. plank, which is used over steel beams, open-truss steel joists, or wood joists, can support similar loads on spans up to 4 ft. Although suitable for floor construction, when the surface is properly protected, plank of this type have their particular application for the roofs of industrial buildings.

Field-poured Gypsum Systems. Gypsum mixed with wood shavings, usually in the proportion of 12 $^1/_2$% by weight of fiber and 87 $^1/_2$% of gypsum, is used for short-span floor and roof construction in the form of slabs, for field pouring. Plywood forms are hung from the steel framing, which can be successfully fireproofed with the same material, or with precast gypsum units manufactured to fit a wide range of structural shapes. Such a design would not be used with reinforced-concrete framing. Slabs poured of the same mixture, or with less wood fiber for the purpose of producing a greater compressive strength, may also be used above open-truss steel joists, spaced not over 36 in. on centers. This design does not require bulb tees. The gypsum slabs 2 to 3 in. thick are always reinforced with welded-steel mesh. For additional information on this subject see *Reinforced Gypsum Concrete*, American Standards Association, A59.1 (1945).

Brick and Structural-clay Tile Arches. These designs are seldom used in modern buildings. In most districts stone concrete, or lightweight-aggregate concrete is far more economical for short-span designs.

Reinforced-brick Slabs. Brick laid on edge with small rods embedded in the mortar joints have been used for short-span structural floor slabs. This system, however, although employed to a limited extent in England, India, and other parts of Asia, is usually uneconomical in the United States.

Steel-plate and Sheet-steel Cellular Floor Systems. Several designs in this group are appropriate for use with structural-steel framing. Although some systems are capable of supporting medium floor loads on spans up to 20 ft, they are most suitable for short-span designs. If the type of occupancy permits the use of a steel ceiling on the soffit of the structural floor, they have an added economic advantage. Short-span designs may be adapted to either light or heavy floor loads. A system providing space for the installation of electric wiring within the thickness of the structural floor is illustrated in Fig. 13. This particular system, which has a broad application for many types of occupancy, has recently been used in a number of large structures, including office buildings, government buildings, and factories.

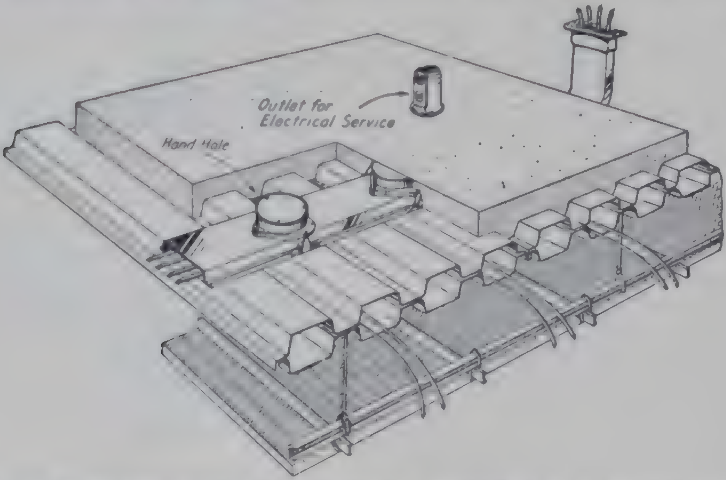

Fig. 13. Sheet-steel cellular floor construction. (Courtesy of H. H. Robertson Co.)

Wood Plank Floors. For industrial buildings such as textile mills, where the weight of the machines, except for looms, is comparatively light, heavy plank may occasionally be used to advantage for structural floors spanning between steel beams if the fire risk can be accepted. Such a floor has the advantage of facilitating the bolting down of machines in any desired location. An automatic sprinkler system would often be installed beneath floors of this type.

FLOOR SYSTEMS FOR TIMBER FRAMING. If wood framing is used with exterior masonry bearing walls, an ordinary wood-joist design is customary except for industrial building or warehouses, where "slow-burning" or mill construction might be used. For structures where timber forms the entire framework, including that of the exterior walls, wood-joist floor construction is generally employed. Such designs, however, are omitted as they have practically no application to industrial buildings.

FLOOR CONSTRUCTION ON OR NEAR THE GROUND. First-story Floors. If the floor system is self-supporting, even if there is no cellar beneath, any appropriate structural system previously described may be used. When framed in wood, it is imperative that the space beneath be ventilated. Ventilation is obtained by openings in the foundation walls or between foundation piers. If continuous walls are used for the foundation, openings of at least 1 sq ft in area should be placed just above grade on all four sides of even small buildings. All openings should be covered by grills. If part of the cellar is fully excavated and contains a heating unit, the heat from this section can be allowed to pass entirely beneath the floor. Such an arrangement obviates the need for openings in the foundation walls and minimizes the need for insulating the floor.

If the floor is laid upon the ground, a concrete slab with a granolithic, or other desired surface finish, is often appropriate. A bituminous compound may be added to the concrete composing the floor slab or incorporated in the finish, to increase resilience. Figure 14, sketches *a* and *b*, show typical details for various conditions. Sketches *b* and *d* show wood flooring supported by sleepers. For these may be substituted a 2-in. thickness of lightweight concrete composed of portland cement and a fine mineral aggregate, forming a base to which a wood floor may be nailed. Wood flooring may also be bedded in mastic, applied directly to the concrete slab. If wood sleepers are used they should be treated with a preservative. Because the elimination of moisture is a primary necessity, a porous fill, composed of cinders or gravel, is recommended even over "dry" soils. Even if floors are laid slightly above the level of the surrounding ground, some of the provisions shown in sketches *c* and *d* of Fig. 14 might be desirable. These two designs, however, have their particular application to basement and cellar floors. Roof water should be effectively diverted from the building by shallow gutters or drains. It is common practice to raise the grade of the ground about 6 in. adjacent to building walls. The surface of the floor slab should be a foot or more above the adjacent ground level, and a greater height may be necessary if the building is located at the bottom of a natural drainage area.

Basement and Cellar Floors. When concrete floors are laid over soil known to remain comparatively dry at all seasons, 4 to 6 in. of porous fill, cinders, gravel, or crushed stone, as in the case of floors slightly above the natural grade, should be sufficient as a base for concrete slabs. Even then, however, it is desirable to provide land tile drains around the building at the footing level. Such a design is particularly appropriate for comparatively shallow basements.

FIG. 15. Arrangement of waterproof membrane for deep basements. (Reproduced by permission from Crane, *op. cit.*)

When concrete floors are laid over soil which is actually wet, or likely to become wet, at certain seasons of the year, the thickness of the fill should be increased to perhaps 12 in.

In extreme cases, parallel lines of land tile are laid beneath the entire cellar area at a spacing of 3 to 4 ft. All land-tile lines should be connected with tight-jointed clay sewer pipe leading to a sewer, storm-water drain, dry well, or, preferably, if grades permit, to the surface of the ground.

In deep cellars, and often in shallow cellars where grades are unfavorable, it may be necessary to install either a sump pit with an automatic electric pump or a complete system of waterproofing. Figure 15 shows typical details. The waterproofing is carried up the exterior walls above any potential water level. If the outside of the basement walls is inaccessible, the same type of waterproofing may be placed on the inner surface and retained by either a masonry or concrete seal. If conditions do not demand membrane waterproofing, less expensive treatments may be applied to either the exterior or interior surfaces.

CONSIDERATIONS AFFECTING THE CHOICE OF THE STRUCTURAL FLOOR SYSTEM. At this stage of the design procedure it will be known whether structural steel, reinforced concrete, or wood is to be used for the structural framing. This fact is one of several guides in selecting the floor system as it has been shown that some systems are not only particularly suited to steel or concrete but also cannot be used except with one or the other. For example, if a building were framed in steel, the floor construction could not be designed as a typical "flat slab" or rigid frame, but any other system mentioned in this book could be used. If framed in reinforced concrete, steel-plate and sheet-steel cellular floor systems would not be appropriate. The selection of the floor system for wall-bearing buildings follows the type of interior framing. For wood-framed structures, wood joists are the normal choice, supported by wood framing or unprotected steel girders and pipe columns.

The size, shape, and continuity of floor panels may influence the choice of the system as the dead load of the heavier designs becomes excessive for long spans. The ratio of length to width of panel usually determines the advantage of a one-way as compared to a two-way system. This same ratio of length to width of panel and the requirements for continuity between at least three consecutive panels may preclude the use of the standard flat-slab design with specified moment coefficients.

The need for structural stability is particularly important for types of industrial occupancy where manufacturing processes cause vibration and would preclude the lighter systems such as the open-truss steel joist. Where the effect of lateral forces, due to wind or earthquakes, is a factor in the design, preference is given to systems that have sufficient strength to act as stiffening elements of the building assembly.

As there is a wide range in the relative fire resistance of the structural floor systems, the designer should choose one that not only meets the demands of the local code, or good practice, for the locality and type of occupancy, but is also consistent with the rest of the construction. This should be done to obtain a favorable insurance rate on both building and contents.

The nature of the under surfaces of the various floor systems should be considered in relation to the ceiling finish. For example, structural clay tile, gypsum, or Haydite block provide an excellent base for two-coat plaster, whereas the metal-pan and steel-joist systems require metal lath to carry the plaster. Solid concrete slabs should not be plastered. If the concrete is poured over well-built forms, two coats of paint, applied by sprayer, can give an excellent surface.

The nature of the floor finish may also influence the choice of a structural floor system and, in particular, the need for concealing electrical conduit or other pipes within the thickness of the floor. Some systems provide space within the structural depth; others require a lightweight fill, 3 or 4 in. deep, between the structural slab and the surface finish. Conduit and small pipes can very easily be embedded in any solid concrete slab. They can be easily accommodated within the depth of open-truss steel joists. The same is true of the precast concrete-joist system unless the plastered ceiling is omitted. It is not generally practicable to place even electric conduit within the ribs of the concrete-ribbed designs, such as the metal-pan and cinder-block assemblies. For these it is usually necessary to increase the thickness of the topping over the pan or block, or to place a fill above the topping.

The weight of the floor system is a minor matter for buildings of only a few stories, but obviously important for higher structures. The thickness should also be considered for buildings of many stories as every inch added to the floor thickness, from the face of the ceiling to the surface of the finish, adds an additional inch to the height of every vertical element in the entire building. Although the relative heat transmission of competing designs is usually negligible for floors, it should be considered if there are extensive areas beneath unheated spaces. The acoustical requirements may occasionally affect the choice of a floor system but would seldom be important except for residential buildings.

A careful analysis of the various possible designs for the structural floor will usually result in reducing the practicable alternates to two or three types. The final step is to make preliminary designs of the proposed assemblies, including the supporting members of the structural frame as well as the actual floor panel. When accompanied by the necessary general information concerning building dimensions and plot conditions, these sketches should enable any competent builder, familiar with local conditions, to make a fairly accurate estimate of cost for each system. From this estimate the designer can make a final decision.

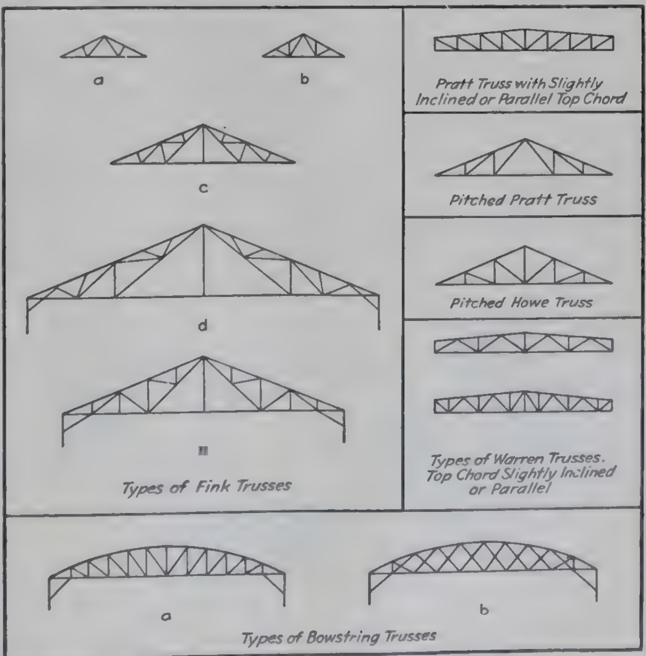
5. SELECTING THE TYPE OF ROOF FRAMING

Except for reinforced concrete used in the form of rigid frames or bents, arches or domes, all pitched and curved roofs are framed in steel or wood. Short spans, particularly over wall-bearing designs, may be supported by steel or timber rafters or wood trusses, with or without a system of purlins. For longer spans, steel or wood trusses, rigid frames and arches of steel, concrete or wood, supplemented by domical forms, may furnish the support for the roof deck. Trusses and rigid frames are particularly appropriate for the wide spans required in factories and hangars.

The framing for flat roofs of multistory buildings often follows the same arrangement as that of the floors below, the final design reflecting the difference in live load. This choice is particularly desirable for multistory concrete structures, in order that the same forms may be used with a minimum of changes. Only where the structural requirements of the roof design are materially different is economy obtained by changing to a lighter-weight design.

The framing for flat roofs of single-story industrial buildings usually comprises some type of parallel chord truss, in wood or steel, with or without purlins between the trusses. Rolled-steel beams of heavy section offer a possible alternate for moderate spans. Reinforced-concrete bents have occasionally been used for long spans. Wood girders are seldom appropriate except in "heavy-timber construction" (see p. 27-20) or where exposed and finished to present an attractive appearance.

STEEL TRUSSES. The more common types of steel trusses are widely used for the roofs of one-story industrial buildings. Figure 16 shows popular designs. It is difficult to make any specific recommendations which would have significance for a particular project as the choice depends on many factors. From a structural viewpoint, however, the following comments may be of help.



a
b
c
d
Types of Fink Trusses
Pratt Truss with Slightly Inclined or Parallel Top Chord
Pitched Pratt Truss
Pitched Howe Truss
Types of Warren Trusses. Top Chord Slightly Inclined or Parallel
a
b
Types of Bowstring Trusses

FIG. 16. Steel roof trusses. (Reproduced by permission from Crane, *op. cit.*)

The Warren truss, with slightly sloped top chord, is often an appropriate choice for spans of 30 to 200 ft, although most economical for spans up to 125 ft. The top chords are sloped from $^3/_4$ to 1 $^1/_4$ in. per ft, a suitable incline for built-up waterproofing.

The Pratt truss, with slightly sloped top chord, may be considered an alternate for the Warren truss, but the latter is often preferred. The Howe truss, with either parallel or slightly sloped top chord, is usually not as appropriate as a Warren or Pratt. Most designers prefer a slight pitch for drainage of roof surface, as the top chords of all these trusses normally serve as direct support for the roof construction. Consequently, those having absolutely parallel chords are not extensively used on spans over 50 ft.

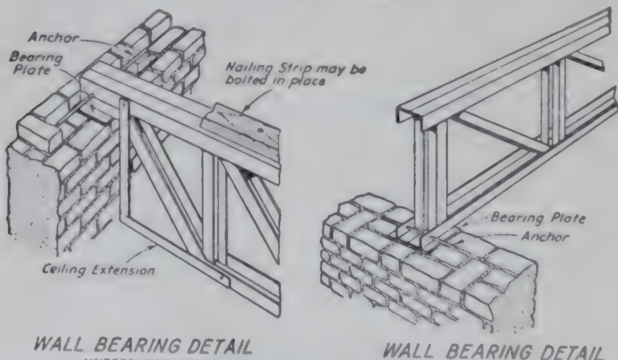
The Fink truss is widely accepted for all types of occupancy wherever a pitched design is desired. It has a particular application for steel-framed mill buildings as a support for steel purlins carrying corrugated roofing or other roof deck. It is particularly economical for spans up to 125 ft. A popular slope is 5 in. vertical in 1 ft horizontal.

Both the Pratt and the Howe trusses, with steeply sloped top chords, are also used for pitched roofs, but they are usually more costly than the Fink. The Pratt would probably be cheaper than the Howe. Where there is no objection to a curved upper chord, the steel bowstring truss is often suitable for moderate spans and has an economic application up to about 125 ft.

The depth of roof trusses, with slightly inclined top chords, supporting only roof loads on a 100-ft span, would be about 11 ft at the center and 6 ft at the ends for both the Warren and Pratt designs. If the chords were parallel, both types would have a depth of about one-twelfth the span. For fairly heavy loads, in addition to the weight of the roof construction, the depth of the parallel chord design might be about one-tenth the span instead of one-twelfth. When supporting only roof loads, the Fink truss will have a depth of about 21 ft, and the bowstring a depth of about 10 ft, for a span of 100 ft.

The spacing of roof trusses is governed by the requirements of the roof construction, the length of span, the cost of foundations, and the loads that the trusses are required to support in addition to that of the roof. In one-story mill-building construction, the length of the typical bay, which determines the spacing, usually varies between 20 and 28 ft. Costly foundations, such as the need for piling, would favor the longer limit. It is also important, in planning manufacturing buildings, to minimize the number of columns wherever this may favor the present or probable future use of the structure. A column once installed is a fixture which requires expensive alterations to remove. Long spans, providing extensive clear floor spaces, are often desirable, notwithstanding a higher first cost.

Provision for expansion or contraction due to temperature changes is important for long, exposed steel trusses resting on concrete or masonry abutments. When framing into steel columns, or resting on top of them, trusses spanning up to 125 ft normally need no special provision for end movement. Where support is furnished by masonry walls or piers, the matter should be considered for spans over 50 ft. There are many instances where much longer trusses have been placed over masonry bearings without causing trouble, but experience dictates caution, particularly in colder climates. In mill-building construction, featuring multiple aisles serviced by cranes, either double columns or a longitudinal expansion joint is often used if the building is over 500 or 600 ft wide. Where it is apparent that movement of a magnitude greater than can be safely absorbed by the supporting assembly may occur, sliding plates or another similar device is required at one end of the truss. The type chosen deserves particular attention, as many designs used in the past have failed to function.



WALL BEARING DETAIL
UNDERSLUNG JOIST

WALL BEARING DETAIL
SQUARE END JOIST

Fig. 17. Open-truss steel joists for wide-span designs. (Courtesy of Ceco Steel Products Corp.)

Supplementing the open-truss steel joists described on p. 27-29, a heavier design is manufactured capable of economically supporting roof loads on spans up to about 60 ft. These units have upper and lower chords formed of hot-rolled structural-steel shapes welded to form a chord section. They vary in depth from 18 to 32 in. and are appropriate for lightly loaded floors and roofs on spans up to fifteen times their depth for the 18-in. size and twenty-four times their depth for the 32-in. size. Typical designs and details of end supports are shown in Fig. 17. These trusses are manufactured with either square or underslung ends; top chords may be either pitched or flat. If pitched, the slope may be toward one end or in each direction from the center. Bridging is essential and is normally placed at approximately 10 ft on centers.

STEEL RIGID FRAMES AND ARCHES. Rigid frames of structural steel are particularly appropriate for spans of about 60 to 200 ft. A common form is illustrated by the familiar aircraft hangar. Types providing exceptionally clear height, to meet the requirements of a particular industry, can be designed with longer legs. Rigid frames of structural steel have a broad application for university field houses, gymnasiums, armories, and amphitheaters, as well as for hangars and industrial plants.

A patented application sponsored by the American Bridge Company is known as the beam-arch construction, although this type is also a rigid frame. The name is derived from the fact that the ends of the beams comprising the principal elements of the assembly are split longitudinally through the webs, and the inner flanges bent to predetermined curves, providing the necessary increase in depth at points of maximum moment. Plates of a thickness conforming to the webs are then fitted into the resulting V-shaped openings. As these are securely welded, or otherwise spliced to the beam webs, they function as an integral part of the expanded beam section.

Field erection is facilitated by shop fabrication in the largest sections that can be transported. Single-span rigid frames are usually designed and erected as two-hinged assemblies. If it is desired to assume a three-hinged condition for dead loads, this may be maintained until the steel work is completely erected by using at the peak of the arch a temporary third pin joint, which is later replaced by riveting or welding. Particularly appropriate for buildings designed for public assembly, the typical form provides an open floor space with unobstructed vision and ample head room. It is structurally applicable to a wide range of roof slopes and to spans up to 200 ft.

Wide-span steel arches are also built of trussed design. They are particularly suitable for hangars, where considerable height is desired. The steel lamella arch, although used for gymnasiums, auditoriums, and restaurants, has little application for industrial work and is less widely used than its counterpart in wood.

CONCRETE RIGID FRAMES. These designs have been used throughout the United States for the roof construction of auditoriums, gymnasiums, hangars, armories, markets, and factories. The structural deck is usually formed of either precast-concrete slabs or concrete poured-in-place, but sometimes the decking is made of wood. Although many rigid frames have been built of greater span, 100 ft is about the economical limit for solid reinforced-concrete sections, as the dead load usually makes one of greater span more costly than a corresponding design in material of a lighter weight.

When comparing the rigid frame in concrete with those meeting the same structural requirements in steel or wood, the choice may be influenced, if not controlled, by the type of occupancy. If either wood or steel must be protected from fire or deleterious gases, the additional cost may be an important item.

Rigid frames of concrete have also been built with hollow sections for both girders and columns. Those employed in one design have clear spans of 77 ft and are spaced 18 ft apart. Precast-concrete joists serve as purlins carrying the roof deck.

CONCRETE SHELL ARCHES. These designs have been widely used for factories, hangars, auditoriums, markets, and sewage-disposal plants. Spans up to approximately 300 ft have been constructed, and longer ones are contemplated. These designs comprise thin, reinforced-concrete curved plates, supported and stiffened when necessary by structural steel or reinforced-concrete framing or masonry walls. Shells may be of single, or multiple span, or various combinations.

The reinforced-concrete columns supporting shell roofs of the multiple barrel and butterfly types usually provide sufficient flexibility to make hinges unnecessary. Stiffness against buckling increases with the curvature of the roof. A strong curvature, however, steepens the section of the shell for some distance above the springing line, and this may result in additional expense for double forms. In some designs, where it is necessary to use a comparatively flat roof with a long radius of curvature, stiffness is obtained either by thickening the shell section or by adding ribs.

For designs of this type, the scaffolds supporting the forms represent a large proportion of the construction cost. Thus buildings of little length are comparatively more expensive than long structures for which the forms may be used a considerable number of times. Both barrel shells and the butterfly design, which is a variation particularly suitable for garages, have been used for industrial plants such as the single-story engineering shop erected at Wright Field during World War II. This building is 360 ft wide and 420 ft long. The roof is composed of nine concrete barrel shells, each of 40-ft span and 3 $^1/_2$ in. thick, except at the haunches, which are 5 in. thick. The columns are spaced longitudinally 56 ft on centers, and the skylight openings are glazed with sandblasted glass. After the shop was built, a Signal Corps hangar was built with the same forms, but the longitudinal spacing of the columns was increased to 120 ft.

Several large hangars, armories, auditoriums, and industrial plants built during recent years illustrate the use of reinforced-concrete arch rings combined with shell construction. The concrete arches should be designed so that the shells comprising the structural slab are supported from the intrados. This arrangement eliminates any projection of structural members below the under surface of the roof and facilitates the movement of the forms as the structure is poured section by section. Shell-roof designs have also been used for domical structures as important as the Hayden Planetarium in New York City, but such applications have little significance for industrial buildings.

The asphalt-mixing plant, erected a few years ago in New York City, comprises four arch rings spaced 22 ft on centers. They have a clear span of 90 ft and a height to the intrados of approximately 85 ft. Concrete barrel arches 8 in. thick were poured between the arch rings, which vary in depth from 6 ft 6 in. at the springing line to 5 ft at the crown. The width of the arches is 2 ft 4 in. at the extrados and 3 ft at the intrados. The change in thickness occurs along the inner face of the barrels and provides a shelf for their support. Structural steel shapes were used to reinforce the arch rings in place of rods or bars. This development, which is comparatively new, eliminated all false work within the structure as the steel served to support the forms. Although not a shell roof, this plant presents an interesting example of designing an enclosed area to meet the requirements of its particular use.

WOOD BEAMS AND GIRDERS. Glued, laminated beams and girders of rectangular section are used for spans up to about 60 ft, but for spans less than 30 ft, solid timbers are usually cheaper except for heavy loads. When the cost is estimated merely on a structural basis, timber girders of considerable span are generally more expensive than steel serving the same purpose. Often, however, they may be economical when employed as a finished product and exposed as part of an architectural treatment. Because laminated beams are manufactured with surfaces machine planed and sanded, they present an attractive appearance. Standard widths vary from 3 $^{5}/_{16}$ to 11 in. with depths as required.

The approximate depth of such units may be roughly estimated from the fact that on a span of 40 ft, with spacing of 14 ft on centers, a uniformly distributed superimposed load of 50 lb per sq ft could be carried by a laminated section 25 in. deep by 9 $^{1}/_{2}$ in. wide. If the span were 60 ft, and the spacing of the beams reduced to 12 ft on centers, the same superimposed load would require a laminated section about 32 in. deep and 11 $^{1}/_{2}$ in. wide. These figures are based on stresses generally accepted for such designs. Beams are usually cambered as the deflection is high.

WOOD TRUSSES. Wood trusses may be supported by steel, concrete, or wood columns or by masonry piers or walls. Solid timbers are widely used except for curved members, such as the upper chord of a bowstring truss. Steel rods are occasionally used for tensile members. Figure 18 shows the more common designs. For spans of 40 to 150 ft, the bowstring type is generally the most economical choice. It has very wide use for roofing industrial structures and is particularly suitable for spans between 80 and 120 ft. In a typical design laminated sections are used for both upper and lower chords; lower chords are often made of solid section.

When supporting a uniformly distributed, superimposed load of 40 lb per sq ft of horizontal protection, bowstring trusses may be appropriately spaced about 20 ft on centers for spans over 60 ft. For spans of lesser length, it may sometimes be economical to use a closer spacing, eliminating the roof joists or purlins, and applying the roof sheathing directly to the top chords of the trusses. On the other hand, for longer spans, trusses are often spaced somewhat farther apart and purlin trusses used to carry the roof deck. Comparative estimates of cost are often necessary to determine which design is more economical.

Bowstring trusses used to support only roof loads on a 100-ft span would have an overall height of about 13 ft. For similar service on a 40-ft span, the height is about 7 ft. For industrial work erected during World War II bowstring trusses were frequently used on spans between 150 and 200 ft, but in some cases the choice was dictated by the need to conserve structural steel. Although one of the more important aspects of modern design is the use of longer spans for both floors and roofs, it should be realized that, from the structural viewpoint, the first cost is definitely greater for long than for moderate spans. If we consider the cost of wooden bowstring trusses on a square-foot basis of roof surface, one well-known manufacturer states that a design suitable for a span of 75 ft might cost 25% more than for a span of 50 ft. Similarly, for a span of 100 ft, the cost of the trusses might be about 50% more than for a 50-ft span.

Used for spans up to about 90 ft but seldom an economical choice beyond 60 ft, Fink trusses are particularly appropriate for pitches greater than 25 degrees. The pitched Pratt and Belgian trusses are used on the same spans as the Fink and are preferable to the latter when the roof pitch is appreciably less than 25 degrees. The pitched Howe truss has been practically replaced by these types in the Tecco connector system of timber construction.

The Pratt truss, with slightly inclined or parallel top chord, shown in Fig. 18*i*, is often economical for spans up to about 120 ft. During World War II spans of 150 ft were used over an aircraft assembly plant. These trusses were 18 ft deep. All these types of wooden trusses can be designed to carry loads resulting from monorails or other factory equipment. The roof deck, composed of solid boards, boarding carried by wood purlins, or any of the appropriate materials described in Article 6, helps to brace the upper chords. Lateral bracing is used between trusses as required by the stress analysis.

Fig. 18. Popular types of timber trusses and typical combinations. (Courtesy of Timber Engineering Co.)

The crescent truss, employing glued, laminated chords, is not widely used but may be economical for spans under 80 ft where increased interior clearance is essential. It was employed in hangar construction for a span up to about 160 ft. In this construction the crescent design was chosen instead of the bowstring as the former permitted the side walls of the hangars to be greatly reduced in height.

The hammer-beam truss is illustrated in Fig. 18 merely for the purpose of identification as ornamental designs of this type have no use in industry. The various combinations of wooden trusses shown in this same illustration have their particular application for one-story factory construction.

For roof spans of 25 to 40 ft, a design identified as the "trussed rafter," may be economical for stores, barns, and some housing projects. It may also have an application for shorter span requirements in industry. These trusses are placed up to 2 ft on centers and surfaced with $^7/_8$-in. boards or other suitable material.

WOOD RIGID FRAMES AND ARCHES. The rigid-frame types of laminated wood sections are particularly appropriate for spans between 30 and 100 ft.

Frames may be spaced 6 to 10 ft on centers and spanned by 2-in. plank forming the roof deck. If this spacing is too close, heavier units may be used and spaced up to about 20 ft on centers. In this case wood purlins, or a type of deck capable of spanning such a distance would be used between the frames. These designs have a broad application for gymnasiums and dance pavilions as well as for hangars and garages. The usual forms for rigid frames and arches, designed of laminated sections, are shown in Fig. 19. For long spans combined with high rise, trussed frames and arches constructed of short-length lumber, joined with bolts and metallic connectors, have been built during recent years for army and navy hangars.

The various arch-rib designs, many of them appropriate for small and medium-sized hangars, are supplied by the manufacturers in two pieces, each half continuous from foundations to roof ridge. For the lighter types they are usually placed on 2-ft centers, and the roof deck is composed of $^7/_8$-in. boards nailed directly to the arch ribs. A design identified as the "tied rafter" is also used on a close spacing for spans up to about 50 ft, or obtained in a heavier design suitable for a 10-ft spacing on spans up to 100 ft. These rafters have their particular application for markets, dance pavilions, and garages, but they might well find their place in industry. The "segment rafter" is another design similarly employed. The lamella arch in steel was mentioned on p. 27-31, but it has been more widely used in wood. Its particular application is for auditoriums and garages. An arrangement of short units, placed in a diamond pattern, is characteristic.

6. CHOOSING THE ROOF DECK

The various types of structural roof systems, or "roof decks" as they are often called, that are most widely used in this country at the present time are described in this article. The term *system* identifies the structural assembly spanning between the framing members such as beams, rafters, or principal purlins. The maximum spans and limiting dimensions conform with standards generally accepted for the various systems, but they should be checked against the requirements of local building codes.

When selecting the floor system, as described in Article 4, the designer was primarily concerned with the material used as structural framing, nature and amount of superimposed load, clear span, degree of fire resistance demanded by building code or good practice, and the general fitness of the design to meet economically the requirements of the entire building. When choosing the deck for a flat roof, we have practically the same considerations except in regard to the live load, which is seldom over 40 lb per sq ft unless designed for occupancy. As used in this book, the term *flat* identifies a horizontal surface or one only slightly sloped, in one or more directions, for the purpose of drainage.

In selecting an appropriate deck for a pitched or curved roof, the same general considerations apply as for flat roofs, but there is often the additional requirement of providing a surface to which the materials comprising the finish, such as shingles or slate, can be easily attached. Precast cement-aggregate slabs and channel sections, corrugated cement-asbestos board, corrugated wire glass, and many sheet-steel designs have a wide application to industrial work. Wood plank of a nominal 2-in. thickness is sometimes used. Many of these types require a waterproof surfacing, whereas others are designed to shed water.

Where a roof surfacing such as slate, asbestos shingles, or clay tile is to be applied, or a wide salvage type of roll roofing, the roof deck must be of a material to permit easy nailing and good nail retention.

Flat roofs, or those sloped only as may be required for drainage, are usually surfaced with a built-up waterproofing and finished with slag or gravel. If the roof is intended for occupancy, the slag or gravel is omitted and the desired surface finish laid over the waterproofing. The structural deck may be formed with gypsum plank, concrete plank, precast cement-aggregate slabs or channel sections, corrugated cement-asbestos board, or some type of sheet-steel assembly. For flat roofs there is also the possibility of using any one of the structural floor systems. If a lightweight design is desired, however, it is usually best to avoid cast-in-place materials. For wood-framed structures, wood-joist construction is often used on short spans and parallel-chord wood trusses for longer spans. Precast cement-aggregate units are occasionally laid over wood framing, but wood boarding, plywood, composition board, or gypsum plank are more appropriate.

The minimum desirable incline for wood, asbestos, or asphalt shingles, slate, and the ordinary types of roofing tile, such as the Spanish Imperial and Mission, is 6 in. vertical to 1 ft horizontal. Wood shingles, however, are often laid on a pitch of 4 in. vertical to 1 ft horizontal. Slate may also be laid to a pitch of somewhat less than 6 in. horizontal to 1 ft vertical, if the "head lap" is increased from 3 to 4 in. For comparatively slight slopes, the slate is laid in bitumen.

"Built-up" roofing, comprising usually either three or four layers of roofing felt, cemented together with coal-tar pitch or asphalt, and surfaced with slag or gravel, is used principally for flat roofs but may be laid on any slope up to 4 in. to 1 ft if "nailability" is provided. This is ordinarily accomplished by using a type of roof deck that has good nail penetration and retention, but the roofing may be nailed into a suitable insulation if the insulation is cemented with bitumen to the roof deck. If the slope is less than 2 in. to 1 ft, nailing is not required. This is the usual condition for flat-roof designs. Roofs sloped more than 4 in. to 1 ft may be surfaced with a wide-selvage type of roll roofing or with a built-up roofing laid in either hot bitumen or cold plastic cement, but without slag or gravel. In both cases nailing is required. Roll roofing has a mineralized surface available in a number of colors. It has been used for roofing concrete arches, for instance, in the field house at Swarthmore College, Pa.

Thin-sheet metals like copper and aluminum can be used on a slope of $^1/_4$ in. per ft or greater, provided the proper type of seam is specified, but they are more appropriate for steeper surfaces. Sheets of corrugated metal and corrugated cement-asbestos board, serving both as a structural roof deck and surface finish, should generally have a minimum slope of 4 in. to 1 ft. Interlocking steel-plate designs, when occasionally used in the same manner without a membrane covering, are difficult to make tight on slopes less than about 3 in. to 1 ft.

As roofs form one of the enclosing surfaces of a building, the heat transmission is important where interior temperatures, appreciably different from exterior temperatures, are to be maintained for extended periods. A low transmission coefficient would obviously reduce the cost for additional insulation. The appearance of the under surface, which varies considerably for different designs, or the probable cost of applying a desired finish is also important for some types of occupancy. The general subject of flashing is discussed on p. 27-51. It does not influence the choice of the structural roof system and should be carefully planned in relation to wall construction. In districts subject to earthquakes, those designs having the stronger connections between deck and framing elements would be preferred. In comparing the advantages of competing designs, the comparative cost of maintenance should be included.

PITCHED-ROOF DESIGNS. Precast Cement-aggregate Slabs, Channel Sections, and Plank. These lightweight units, composed of portland cement and aggregates such as Haydite, cinders, slag, or slag products, are widely employed for structural roof decks over steel framing. Slabs of uniform thickness, channel, or rib sections are used. They are generally placed on a purlin spacing up to 12 ft, but the heavier units can carry normal roof loads on spans up to 20 ft. All are thoroughly reinforced. When nailing is required, the slabs are cast with a special material $^1/_4$ in. thick applied monolithically to the top surface. Some designs furnish a layer of insulating or acoustical material cast integrally with the concrete on the underside. Tile are also manufactured with glass panels.

Precast slabs of chemically expanded concrete are also manufactured in both plain rectangular section and channel design. For example, one manufacturer supplies plain slabs 24 in. wide and 2 to 3 $^1/_2$ in. thick which are suitable for normal roof loads on spans 5 to 6 ft between purlins or other supports. Channel sections are of the same width and 3 $^1/_2$ in. deep for spans carrying only light loads up to 10 ft. All are thoroughly reinforced.

These designs compete with those employing Haydite or other lightweight aggregate without an aerating compound or special process.

Lightweight concrete plank, described on p. 27-50, are also suitable for pitched roofs. As the material is "nailable," any desired surface finish may be applied.

Corrugated Cement-asbestos Board. This material is usually composed of about 85% portland cement and 15% by weight of asbestos fiber. It is fire resistant, and it has low heat transmission and good surface reflection. The average thickness is $^5/_8$ in.; sheets are usually 3 ft 6 in. wide with lengths varying from 3 to 10 ft. Weight is about 4 lb per sq ft. The maximum purlin spacing for standard types is 4 ft 6 in. Sheets are lapped one corrugation at sides and 6 in. at ends. They can be used without other covering for roofs having a minimum slope of about 3 in. vertical to 12 in. horizontal, but a steeper pitch is preferable. When used over steel framing they are attached to purlins by means of clips and bolts. Units of the same material are furnished for ridges, eaves, and other special requirements. Although this type of roof deck has been used for gymnasiums, auditoriums, and even small residential buildings, it is particularly appropriate for industrial structures.

Corrugated Wire Glass. Two types of glass are available: the white and the actinic, which has an amber color. The latter diminishes the effect of the radiant heat from direct sunlight. Both types are furnished in widths of about 2 ft 4 in. and of a suitable length to span between purlins spaced up to 5 ft on centers. Corrugated glass should not be used on slopes less than 4 in. vertical to 12 in. horizontal. At least this pitch is essential to permit the condensation gutters to function. When properly installed, the surfaces are practically self-cleansing. The corrugated glass panels are not lapped at the sides but placed $^1/_2$ in. apart with a metal cover cap over the joint. Caps may be of galvanized steel, copper, aluminum, Monel metal, or stainless steel. The same metals are employed for ridge caps and other special requirements. The sheets are lapped 3 in. at the ends and are attached to the purlins either by clips or by bolts. This type of roof deck has a general application wherever daylighting is essential. It is widely used for large skylights and sawtooth construction in industrial buildings and is also appropriate for museums and art galleries.

Corrugated metal sheets, supported by steel purlins or steel or wood rafters, are often used for roof decks in cheaper types of industrial work. Corrugated galvanized steel or iron is generally available in standard-sized sheets. Zinc alloys furnish a more durable surface which does not require painting. Cold-rolled hard copper has also been used, but a copper-clad corrugated steel sheet, with a layer of asbestos felt cemented with asphalt between the two metals, is more popular. The asbestos felt is helpful as insulation. Other types comprise corrugated sheets surfaced with a bitumen and felt, factory-applied sealing coat.

A purlin spacing of 2 ft 6 in. is required for plain corrugated copper sheets of 16-oz weight, but a purlin spacing of 5 ft is appropriate for the standard-weight steel and zinc alloys. The side connections between sheets, which vary in width from 2 to 3 ft, are generally made by lapping the corrugations. At the ends, sheets are lapped 4 to 6 in. Sheets may usually be obtained of any desired length up to 10 ft. The built-up designs, comprising corrugated steel, insulation, and surface protection are superior to those of bare steel in permanence and heat transmission. For these types, the purlin spacing varies with the gage of the metal; 10 ft would be appropriate for 18 gage and 7 ft for 24 gage. Some of the more modern steel-deck designs are appropriate for the pitched roofs of industrial buildings. As their chief application is for flat roofs, however, they are described on p. 27-37. The thin sheet metals, such as copper and aluminum, except the corrugated designs mentioned above, are used for surface finishes and not for structural roof decks.

Designs for Wood Framing. Wood plank of a 2-in. nominal thickness is sometimes used for steel-framed, pitched roof decks with a purlin spacing up to 6 or 8 ft, but is more appropriate when the support is furnished by wood trusses, arches, or rigid frames of wood. For buildings framed entirely of wood and for wall-bearing construction where wood is used for the interior support, the same material is appropriate for the roof framing. Structural designs of this type are well standardized and appear in many reference books. The roof deck, supported by wood rafters, may be of solid boarding, plywood, shingle lath, or various composition boards such as laminated Sheetrock. The roof boards are usually matched, either tongue-and-groove or shiplap. A $^7/_8$-in. thickness is standard.

When slate, tile, or asbestos shingles are used as a surfacing material, over the roof deck, a layer of roofing felt and sometimes insulation is placed between the two. If Sheetrock is used, it should be protected from rain by either built-up waterproofing or a type of roll roofing. Corrugated sheets of steel, asbestos-protected steel, copper, zinc, corrugated asbestos board, or corrugated glass can also be used over wood rafters, but they are usually supported by structural steel framing.

FLAT-ROOF DESIGNS. Precast Gypsum Tile and Plank. The most popular gypsum unit for flat roofs is the plank. Standard sizes are 2 in. by 15 in. by 10 ft and 2 in.

by 15 in. by 8 ft. The plank are reinforced with welded, galvanized steel mesh. The edges are steel bound and of tongue-and-groove design. Assembly is by clips to the supporting purlins, which are spaced 30 in. to about 6 ft, as required by the superimposed load. The plank weigh 12 lb per sq ft. After erection the plank are surfaced with a built-up waterproofing. Insulation is placed between if required. Light weight and ease in erection make them very popular for industrial use, but the under surfaces are vulnerable to moisture. Although much less widely used for industrial roofs than the gypsum plank, any type of precast gypsum unit that is suitable for pitched roofs can also be used on flat roofs. Nailing facilities are obviously unnecessary.

Precast Cement-aggregate Units. Many types of precast cement-aggregate units described on p. 27-35 as suitable for pitched roofs can also be used on flat roofs. The Flexicore slab already discussed is an example. Built-up waterproofing is required over the roof deck. As nailing is not necessary, stone-aggregate slabs may be used, but those composed of Haydite and similar lightweight aggregates are more popular.

A lightweight, tongue-and-groove plank, cast with cinders or blast-furnace slag, is widely used. These units, which are 2 or 2 $^{3}/_{4}$ in. thick, may be obtained in appropriate lengths conforming with a desired purlin or rafter spacing. The weight of the 2-in. plank is 13 lb per sq ft and it may be placed on a purlin spacing of 7 ft for superimposed loads up to about 50 lb per sq ft.

Slabs composed of mineralized wood fiber, combined with portland cement to form a porous and fire-resistant unit, are identified by the manufacturers as Porex. They are useful for both heat insulation and sound absorption. For slabs 1 ft 10 in. wide and 1 $^{3}/_{4}$ in. thick, a subpurlin spacing of 22 in. would be appropriate. The total weight of this design, including $^{1}/_{4}$-in. cement-mortar finish and subpurlins, spanning up to 8 ft, is about 9 lb per sq ft of roof surface. Products of this type have been shipped to many sections of the country, but as all are manufactured in New Jersey, the designer should check their availability before planning to use them.

Cemesto board is composed of Celotex cane fiber surfaced on both sides with $^{1}/_{8}$-in. cement-asbestos board. The standard width is 4 ft, and lengths vary from 4 to 12 ft. The 1 $^{9}/_{16}$-in. and 2-in. thicknesses are used for roof decks. Corresponding weights are 4.8 and 5.3 lb per sq ft. A 4-ft purlin spacing is often used. Support may be furnished by rolled-steel sections or open-truss steel joists.

Corrugated Cement-asbestos Board. This material is appropriate for flat roof decks when one or more layers of rigid insulation are laid over the corrugations to provide a smooth surface for the application of built-up waterproofing. Additional insulation is often obtained by filling the corrugations with an insulating material.

Steel Roof Decks. Designs composed of interlocking plates have a particularly broad application for one-story industrial buildings. They are economical in first cost, speedily erected, and some types may be combined with any required degree of insulation or acoustical treatment applied to the under surface. Built-up waterproofing is required.

The units comprising a steel deck vary considerably in the different designs. Usual widths are between 12 and 16 in., depths of ribs 1 $^{1}/_{2}$ to 2 in. for the shallower or lighter types and 3 to 5 $^{1}/_{2}$ in. for those intended for longer spans. Manufactured of copper-bearing steel or iron, the different styles vary in weight from about 200 to over 600 lb per 100 sq ft. Thicknesses vary from 22 to 16 gage. The 18- and 20-gage thicknesses are particularly popular. Their respective weights are about 320 and 240 lb per 100 sq ft of roof surface. Sheets are welded to steel beams or purlins. The lighter designs are used on spans 4 to 5 ft, and the heavier types on spans up to 25 ft to support a superimposed load of 50 lb per sq ft. Plates usually span over several purlins and are lapped or otherwise joined to form a tight, continuous surface. Special plates are provided for ridges and valleys, monitors, and saw-tooth designs. The lighter types may be bent to form a curved surface where the radius is not less than 60 ft.

Installing with ribs up provides a smooth steel ceiling on the soffit but requires sheathing on top which may be in the form of steel or iron sheets, wood, or preferably a rigid insulation laid over the tops of the ribs to serve as a base for the built-up waterproofing. If the units are assembled with ribs down, an advantage is that a smooth top surface is available to support the waterproofing. If the appearance or sound reflection of the ribbed ceiling is objectionable, various combinations of acoustical materials or additional insulation may be applied to the lower surface. A design employing Fiberglas has been used for industrial buildings to provide low heat transmission, excellent sound absorption, a surface which greatly assists in shadowless lighting, and one which can be made both fire and shatter resistant. With slight modifications to meet special conditions, this assembly has been used successfully in a number of manufacturing plants.

Designs for Wood Framing. Roof decks of flat-roofed buildings framed in wood are ordinarily supported by wood-joist construction similar to that used for the floors. The structural surface is sloped to provide drainage. Wood board, plywood, various composition boards, and gypsum plank may be used for the roof deck. Built-up waterproofing would be laid over any of these surfaces. The lighter precast units of cement-aggregate composition can also be placed over wood joists but are less appropriate than for steel framing.

HEAT TRANSMISSION AND INSULATION. When comparing the characteristics of competing roof systems it is often desirable to investigate their relative resistance to the passage of heat. For this reason a *résumé* of the subject, together with a brief discussion of the principal types of insulating materials, is given in this article. No tables of heat-transmission coefficients are included as they may be found in the current edition of the *Guide*, yearly publication of the American Society of Heating and Ventilating Engineers, and in the *Power* Volume of Kent's *Mechanical Engineers' Handbook*, pp. 12-02 to 12-12.

Heat Losses and Heat Gain. If interior temperatures are appreciably higher or lower than exterior temperatures, insulation is often necessary to reduce the heat loss in cold weather or the heat gain in hot weather. The principal means by which heat passes through the envelope of a building are:

1 The infiltration of air through cracks due to faulty construction or the normal leakage along contact faces of operating sash and doors, obviously minimized by careful fitting of all elements comprising the building envelope.

2 By transmission through the enclosing surfaces of the building. For example, if the structural roof were composed of concrete, with a hung ceiling below, heat would pass through the plaster of the ceiling by conduction. It would then cross the air space between ceiling and slab by radiation, conduction, and convection. Passing through the concrete slab by conduction, it would leave the surface by radiation, conduction, and convection.

For homogeneous materials conductivity varies with their density and the amount of moisture contained. In general, it is higher for the more dense materials, but for some of fibrous composition there are optimum densities for lowest conductivities. The amount transferred from a surface by radiation depends upon the emissivity of the surface as well as the temperature difference between the boundaries of the air space across which radiation takes place. Both conduction and convection are influenced by the width and shape of the air space, the amount of air movement within the space, and the roughness of the boundary surfaces.

A large proportion of the total heat transferred across air spaces, such as exist in furred walls or between the joists of roof construction, may be by radiation. This fact indicates the value of metallic surfaces such as aluminum foil and specially coated sheets of steel having capacity to reflect heat rays. Although the transfer or radiant heat is not greatly influenced by width of such a space, it should be at least $^3/_4$ in. wide in order to limit the total conductance. In referring to heat-reflective materials it is undesirable to use the term *brightness;* the important characteristics are emissivity and reflectivity.

Types of Insulating Materials. There are two main groups. The first comprises those which offer resistance to the passage of heat by conduction as they have low density and comparatively low conductivity. The second group comprises metallic surfaces used as boundaries of air spaces within the construction of walls, ceilings, or roofs. The first group is divided into three classes: rigid insulation, flexible types, and insulating fills. The second group has no subdivision, but various metals are used to accomplish the same purpose, which is the reflection of radiant heat waves.

Rigid Insulation. This is generally in the shape of boards $^1/_2$ to 1 in. thick or blocks 1 to 4 in. thick. One variety is composed of wood, cane, and other vegetable fibers pressed into sheets sufficiently rigid to be nailed upon joists or studding, or laid over a roof deck beneath built-up waterproofing. Pressed cork, Foamglas, and mineral wool are also available in blocks varying in size from 12 by 18 in. to 12 by 36 in. and in thicknesses from 2 to 6 in. Cork has a wide application to low-temperature installations. When laid upon a roof deck these blocks are set in coal-tar pitch or asphalt.

The thinner types of rigid insulation, particularly the fiber boards, may be used as a base for plaster on ceilings or exterior walls, and some are attractively finished on one face for use as exposed interior surfaces. Others are coated with bitumen or enclosed in waterproof paper to prevent the passage of water vapor. At least one type is furnished with aluminum foil applied to one surface in order to combine the function of low heat conduction with the reflection of radiant heat.

Flexible Insulation. Varieties in this group may be composed of organic materials, such as wood fiber and cotton, treated in a manner to render them very light and fire resistant. Another type is derived from inorganic materials and identified as rock or glass wool. Mineral wool is composed principally of silicates of calcium and aluminum.

It has the appearance of loose wool or cotton. Rock wool is made from natural rock or a combination of limestone and shale. Slag wool is derived from iron, copper, or lead blast-furnace slag. Glass wool is made from silica sand, soda ash, and limestone.

These materials are furnished in the form of batts, blankets, or quilts as may be required to fit the spaces where insulation is to be placed. The thicknesses vary from 2 to 4 in. Waterproofed paper is often applied to one or both surfaces for the purpose of excluding moisture. Insulation of this type is not sufficiently rigid to be used beneath built-up waterproofing but has a wide application between wood studs in exterior wall construction and between the joists of flat roofs and rafters of pitched roofs. Although most widely used with wood-framed construction, it is also appropriate between furring strips on the inside of masonry walls and between floor or roof joists in steel-framed assemblies. In the steel-framed assemblies definite provision should be made for attachment. When installing either the rigid or flexible type of insulation, it is important to avoid any cracks between the sheets, batts, or blankets through which heat transfer can occur.

Insulating Fills. Over concrete roof decks various types of granular materials, often the size of small pellets, are used for the purpose of insulation. Several of the newer varieties are derived from expanded mica and diatomaceous earth. Pumice is used for the same purpose. When applied over a roof deck, these materials are usually mixed with portland cement. However, they also have a wide application as merely loose fills in locations where it would be difficult to install other types of insulation.

Precast concrete roof slabs are manufactured containing a vermiculite composition which provides considerable insulation. Although most widely used as a fireproofing material, vermiculite plaster has a high heat insulating value and may be employed for this purpose where plaster applications are appropriate. The word vermiculite identifies a group of minerals derived from certain varieties of mica.

Reflective Insulation. Several types of metals are used for this purpose. Aluminum foil mounted upon a strong paper backing is an example. Thin sheets of steel, finished to a dull luster, are also effective and have an application for low-temperature installations. These materials are installed as one of the boundaries of an air space which should be at least 3/4 in. wide. The better types maintain their effectiveness under service conditions.

CONDENSATION AND VAPOR SEAL. Two possibilities for condensation exist under normal conditions of occupancy. (1) Moisture may form on the interior surfaces of roofs, ceilings, or walls. It is referred to as surface condensation. (2) Moisture, in the form of water vapor contained in the interior atmosphere of the building, may penetrate the enclosing surfaces and condense within the roof or wall assembly. It is referred to as interstitial condensation.

Surface Condensation. Surface condensation may present a serious problem in factories where the manufacturing process produces high humidities. It can be eliminated by either reducing the relative humidity of the interior or maintaining the interior surfaces of the enclosing elements above dew-point temperature. If the second alternative is necessary, the chart (Fig. 20) will indicate the permissible relative humidities for various transmission coefficients and outside temperatures ranging from minus 30 to 40 F. The dotted line indicates the permissible relative humidity (64%), if surface condensation must be avoided, for an exterior wall or roof having a transmission coefficient of 0.26, when the exterior temperature is minus 10 F.

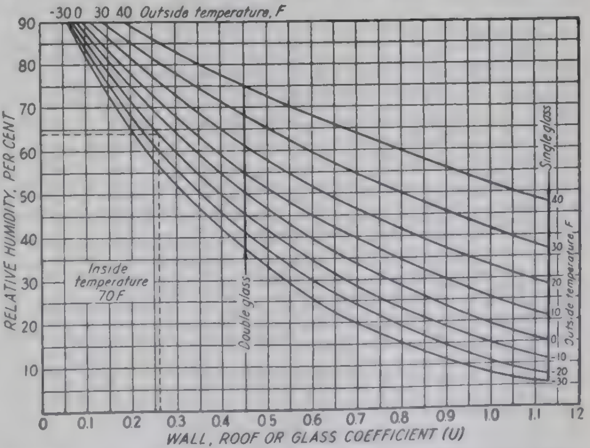

FIG. 20. Permissible relative humidities for inside temperature 70 F and various transmission coefficients. (Reproduced by permission from *Heating, Ventilating, Air Conditioning Guide*, 1946, Chapter 6)

Interstitial Condensation and Vapor Seal. Even with interior temperatures such as are normally maintained within a building during the heating season, if combined with a moderately moist atmosphere, such as 30% relative humidity, there may be a higher vapor pressure within the building than outside. As water vapor passes very easily through most building materials, it may enter the surfaces of plastered ceilings or walls. On its way through the roof or wall construction, a colder zone is reached and the temperature of the moisture-laden air is lowered to the dew-point, resulting in condensation. Condensation has often caused not only the discoloration of interior surfaces but also serious deterioration of insulating materials.

The lowering of the relative humidity of the interior atmosphere would lessen the probability of interstitial as well as surface condensation, but moderately high humidities are often desired and, even where not provided intentionally, may be caused by conditions of occupancy. As it is usually impracticable to permit the free passage of water vapor through walls and roofs, because of the need of minimizing heat losses, some definite provision must be made to obviate this condition. Ventilation between roof joists, or in the open spaces occupied by the trusses supporting the roof deck, is the most effective means. It is particularly recommended in sealed-off spaces beneath steel roof decks. If ventilation is impracticable, the most effective means of guarding against condensation, within either roofs or walls, is to introduce a barrier formed of a material offering a high resistance to the passage of water vapor.

Such a barrier should be placed as near as practicable to the interior surface. It is imperative that it be installed on the warmer side of the insulation. If roofs are framed in open-joist construction, wood or steel, the seal may be in the form of a glossy-surfaced asphalt-impregnated and surface-coated sheathing paper, weighing at least 50 lb per 500 sq ft. Such paper should be applied directly to the underside of the joists or rafters immediately above the plaster or other interior finish. Sheets should be well lapped with mastic applied at all joints. The same type of seal may be used above a hung ceiling. Somewhat less effective are various brush or spray applications of a vapor-resistant finish applied to the interior surface of a ceiling or wall.

For the typical flat-roof designs of fire-resistant buildings, where a reinforced-concrete slab forms the structural roof deck, a vapor seal should be placed on top of the slab beneath the insulation. It may be formed with two plies of impregnated roofing felt, laid in hot asphalt or coal-tar pitch. As some moisture may pass through this seal and be prevented from escaping by the four-ply built-up waterproofing, which would normally form the exterior surface of such designs, a type of insulating material should be chosen which will not absorb moisture or deteriorate when exposed to dampness. A critical condition has occurred in many cases where promenade tile have been used as a wearing surface over the built-up waterproofing. In some instances sufficient deterioration has taken place to require a complete resurfacing of the roof. It has occasionally been considered desirable even to remove the promenade tile and cover the roof with ordinary slag or gravel, or a colored aggregate, such as ground slate, to give a more attractive surface finish.

CONSIDERATIONS AFFECTING THE CHOICE OF THE ROOF DECK. For flat roofs of multistory buildings, it is generally appropriate to use the same framing materials and often the same structural system as for the floors, unless there are large skylights or other special requirements which make such a choice impracticable. The flat roofs of single-story buildings and all pitched roofs are normally framed in steel or wood, except for the wide-span designs in concrete such as the arch or rigid frame. In all cases, the spacing of supports should provide economical spans for the selected type of roof deck. The limiting spans for which the different designs are suitable have been given in the preceding descriptions. The longer span systems obviously reduce the number of purlins or beams. If a sawtooth design is required, a system should be chosen that is adaptable to this purpose to avoid introducing dissimilar types of construction. In districts subject to high winds or the danger of earthquakes, the strength of the connections between the various parts of the roof assembly should be studied.

For some types of industry, the cost of providing adequate fire resistance may be a controlling factor in the choice of the roof assembly. This is particularly true if it is necessary to fireproof steel trusses and may lead to the consideration of designs comprising the shell arch or other reinforced-concrete forms. The weights of the different types of roof deck have been given in the previous descriptions. They may favor one system at the expense of another, as reflected in the steel tonnage or cost of other supporting material. For certain classes of occupancy appearance may influence the choice. Some assemblies are more attractive than others, and some offer superior facilities for applying ceiling finishes.

There is considerable difference in the heat transmission of various roof assemblies. The lightweight porous materials are generally superior in this respect to those that are more dense, such as stone concrete. Some designs comprising especially processed lightweight cement-aggregate units have considerable insulating value. The unprotected sheet metals, on the other hand, are particularly undesirable. The steel deck requires considerable insulation for most classes of occupancy. In comparing competitive designs the relative heat loss should be roughly checked as the cost of insulation may be an important factor. The extent to which a roof surface is capable of reflecting, rather than absorbing, the radiant heat from the sun is also worthy of consideration for systems that serve both as structural deck and surface finish. In buildings where the manufacturing process either requires or produces a relatively high humidity, the designer should beware of choosing materials susceptible to moisture. As previously mentioned, it is always desirable to use an insulating material that will not deteriorate in the presence of moisture or show any appreciable degree of absorption.

The selected roof assembly should provide for the application of the desired surface finish. Because of the extensive use of built-up waterproofing for flat roofs, this feature has little importance except for pitched roofs. Fortunately, the various plank, slab, and channel designs of gypsum or cement-aggregate composition are available with surfaces prepared for nailing to which slate, clay tile, and similar materials may be attached. Some designs, however, offer better facilities than others. Durability has its particular application to roof surfacing materials rather than to the structural roof deck. It should be considered for systems that serve both purposes such as the red-tile and corrugated cement-asbestos board, and where manufacturing processes cause critical exposures. The cost of maintenance is often an important item for extensive roof areas and should be estimated for competing designs. This item has particular significance, as previously noted, when comparing the advantages of a one-story and multistory industrial building.

An analysis of the various possible systems that may be employed for the structural roof deck will usually result in reducing the practicable alternates to two or three designs at most. Comparative estimates should then be made as in floor construction.

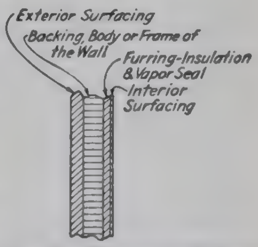
7. CHOOSING THE WALL CONSTRUCTION

There are many types of wall and partition construction which differ widely in architectural appearance, structural characteristics, fire resistance, and heat and sound transmission. Their relative advantages for a specific project may be compared by making a functional analysis. For this purpose any type of wall from the primitive adobe of the Southwest to the complex assemblies including exterior facing, masonry backing, furring, and plaster, typical of our larger cities, may be analyzed (see Fig. 21). The following characteristics are always essential.

1. Exterior surface should be reasonably resistant to atmospheric conditions and have an acceptable appearance; in combination with the other elements of the assembly, it must be rain- and windproof.

2. Body, backing, or frame of the wall, in combination with the other elements of the assembly, must be structurally adequate to support its own weight, resist all applied forces, often transmitting them to the other elements of the structural frame, and provide the necessary fire resistance.

3. Insulation from cold or heat and adequate provision against condensation of water vapor, either on the inner surface or inside the wall, appropriate for the locality and type of occupancy, should be furnished. It may also be desirable to compare the sound transmission of competing designs.



Exterior Surfacing
Backing, Body or Frame of the Wall
Furring-Insulation & Vapor Seal
Interior Surfacing

FIG. 21. Diagrammatic section of an exterior wall. (Reproduced by permission from Crane, *op. cit.*)

4. Interior surfaces should meet the utilitarian demands of occupancy, including, where necessary, light reflection and suitable sound absorption. They should also have an acceptable appearance.

5. The wall assembly which satisfies these requirements at the lowest first cost and expense for maintenance will generally be the best choice.

In the conventional residential and commercial designs, different materials are used to meet these demands, but for some types of structures a far simpler wall section may serve the same purposes. For example, an 8-in. reinforced-concrete panel wall may often be used for industrial buildings. Good concrete is reasonably resistant to atmospheric conditions. If cast in well-constructed forms, the exterior surface may be satisfactory without finish. If well designed and well built, such a wall is durable and rain- and windproof. An 8-in. thickness should meet all structural and fire-resistance requirements. For many industrial buildings no special insulation is necessary. If the interior concrete surface is acceptable for industrial occupancy, this simple concrete section may meet every requirement demanded of the more complicated wall designs.

DEFINITIONS. The following definitions are abstracted from *A Glossary of Housing Terms*, Building Materials and Structures Report BMS91, National Bureau of Standards, 1942.

Bearing wall is a wall that supports any vertical load in addition to its own weight.

Common wall is a wall owned by one party but jointly used by two parties, one or both of whom is entitled to such use under the provision of a lease.

Curtain wall is a nonbearing wall between columns or piers that is not supported by girders or beams.

Enclosure wall is an exterior nonbearing wall in skeleton construction anchored to columns, piers, or floors, but not necessarily built between columns or piers.

Exterior wall is any outside wall or vertical enclosure of a building other than a party or common wall.

Fire-division wall is a wall that subdivides a building to restrict the spread of fire, but is not necessarily continuous through all stories or extended through the roof.

Fire wall is a wall that subdivides a building to restrict the spread of fire. It starts at the foundation and extends continuously through all stories to and above the roof.

Foundation wall is a bearing wall or pier below the first-floor construction.

Nonbearing wall is a wall which supports no vertical load other than its own weight.

Panel wall is a nonbearing wall in skeleton construction built between columns or piers and wholly supported at each story.

Parapet wall is that part of an exterior, party, or fire wall extending above the roof line.

Partition is a wall that subdivides spaces within any story of a building. If designed to restrict the spread of fire, it is called a **fire partition.**

Party wall is a wall used jointly by two parties under easement agreement and erected at or upon a line separating two parcels of land that may be held under different ownership.

Retaining wall. (1) Any wall subjected to lateral pressure other than wind pressure. (2) A wall built to support a bank of earth.

Spandrel or spandril is the panel between the top of a window or door at one story and sill of a window or door at the story above.

MASONRY WALLS. All materials used in masonry wall construction should meet the requirements for strength and durability demanded by good practice or mandatory code. As mentioned on p. 27-10, the *American Standard Building Code Requirements for Masonry*, 1944, furnishes an excellent standard for such designs. Because in this country masonry bearing walls are used only for comparatively low buildings, the minimum thicknesses demanded by building codes or common practice usually result in adequate structural strength. Consequently, the most important requirement for exterior walls above grade is often impermeability to wind-driven rain. This fact has not been sufficiently emphasized in either the specification or the supervision of masonry.

Specification of Materials. The quality of materials should conform with the appropriate standard of the American Society for Testing Materials. As constant changes are being made in the specifications no revision would have more than temporary significance. The designer has the option of obtaining the current designation from the publications of the Society or merely stating that the latest revision shall apply.

The recommendations in the following articles have a general application to all masonry assemblies when used in exterior wall construction. It is important that the materials not only should conform to the mandatory or accepted standards but also should be chosen for the purpose of obtaining a wall section impervious to wind-driven rain. For example, in specifying mortar, it is highly desirable to choose a type of lime which, with the selected proportions, will produce a satisfactorily high water retentivity. This requirement favors the better grades of pulverized quick lime made into putty or type S mason's hydrate, rather than the standard variety of hydrated lime identified as type N. Either choice would meet any requirement of building code or common practice, but the first definitely facilitates laying a water-tight wall.

Although it is necessary to forbid the use of bricks which do not conform to the requirements for grade SW (ASTM C62-44) in locations where they may be frozen when saturated, those having an absorption as high as 17 to 20% * have been used successfully in exposed walls in both Chicago and New York City. It is essential, however, that their suction rate be reduced to a satisfactorily low limit before they are laid. The suction † of the bricks when placed in the wall, rather than their total absorption when dry, affects the permeability of the masonry.

In some sections of the country a white powdery deposit, generally referred to as efflorescence, occurs on the outer face of exterior brick walls. It is caused by the action of water penetrating the wall and dissolving salts contained in the mortar or masonry units. In order for efflorescence to occur, soluble salts must be present in the wall materials, and the construction must permit water to enter the wall, dissolve the salts, and then carry them to the surface, where evaporation results in their deposit. Most clay and shale brick manufactured in this country do not have this efflorescence, but in some localities efflorescence presents a serious problem. Any masonry unit may be easily tested by partial immersion for a period of one week in distilled water. If there is likelihood of efflorescence after incorporation in walls, it will show on the surface of the sample. Efflorescence may be removed from the face of a wall with a solution of one part commercial muriatic acid mixed with ten parts of water, applied by means of a fiber brush. Walls should be thoroughly washed with water both before and after scrubbing with this solution. Such a treatment is seldom of more than temporary value.

---

* Percentage by weight after 5-hr boiling.

† *Brick suction* is defined as the amount of water in grams or ounces absorbed by a brick (30 sq in.) placed on the flat side in water to a depth of 1/8 in. for 1 min.

As most varieties of light-colored stones commonly used for wall facing or veneer become discolored or otherwise injured when brought in contact with standard portland cement, such masonry units should always be set in a mortar containing a white or nonstaining cement. The lime should also be of a type incapable of causing injury to the stone. In order to break the contact between the facing of a masonry wall and the backing (the backing is normally laid in mortar containing standard portland cement), the backsides of the facing units, including bond stones, should be coated to a depth of $^1/_2$ to $^3/_4$ in. with a layer of the same nonstaining mortar used for the facing. The operation is called *parging*. (See p. 27-44.)

Proportions for Mortars. Provided that the ingredients of the mortar and the proportions of the mixture meet building code requirements or accepted standards for structural strength, the designer is primarily concerned with obtaining a "workable" mortar that will facilitate the laying of the masonry units. There is no nationally accepted test for workability, but it is closely related to the water retentivity of the mixture, which can be checked by reference to the Federal Specification for Masonry Cement, SS-C-181. In the following recommendations all proportions are by volume, and sand or other aggregate is measured in a damp and loose condition which conforms to usual practice on the job.

If the essential requirement for the masonry is structural strength or durability to resist alternate freezing and thawing in the presence of moisture, a mortar containing a relatively high proportion of portland cement is desirable. A good mixture is: 1 part portland cement : $^1/_4$ part lime putty : 3 parts sand. This mortar has a somewhat lower workability than would be chosen if less strength were demanded, but it is still workable and is appropriate for foundation walls composed of hollow masonry units, for the thinner cavity wall designs, and where strengths comparable to that shown in Table 12 for type A mortar is demanded by the design. The cost is generally more than for a mortar containing a higher proportion of lime and sand, which is preferable where high strength is not necessary.

For masonry walls above grade, where the essential requirement is impermeability to wind-driven rain, a mortar having greater workability is desirable. A good mixture is: 1 part portland cement : 1 part lime putty : 5 to 6 parts sand. Such a mortar is suitable for all general purposes except where one of higher strength is definitely required. It is an appropriate choice for foundation walls laid with solid masonry units, load-bearing walls of solid units above grade, and often for isolated piers above grade. It may also be used for hollow masonry units, hollow walls of solid masonry units, and cavity walls more than 10 in. in nominal thickness. It would not be appropriate for use in districts where the earthquake hazard demands that masonry have a higher structural strength than required elsewhere. It would not be appropriate for gypsum blocks that are laid in gypsum mortar, and it should be remembered that special mortar mixtures are used with refractory cements.

Except for the specially processed hydrates, lime should be used in the form of putty. This is, of course, necessary for the quick limes, but it is also desirable to do it when the ordinary hydrates are used. The resulting mortar is more workable.

As an alternate to this last specification, the designer has the option of choosing a masonry cement such as that identified by Federal Specification SS-C-181b, Type II, or a natural cement conforming to ASTM Specification C-10-37. As the natural cements may be included in the general classification of "masonry cements," they are not specifically mentioned in Table 11. The usual mixture is: 1 part cement : 3 parts sand. Such mortars

Table 11. Volumetric Proportions for Masonry Mortars

(From *American Standard Building Code Requirements for Masonry*)

Mortar Type	Cement	Hydrated Lime or Lime Putty, Allowable Range	Aggregate, Measured in a Damp and Loose Condition
A	1 (portland)	0 to $^1/_4$	Not more than 3
B	1 (portland)	1 to 1 $^1/_4$	Not more than 6
B	1 (masonry FS type II)	....	Not more than 3
C	1 (portland)	2 to 2 $^1/_2$	Not more than 9
C	1 (masonry FS type I)	....	Not more than 3
D	0 to $^1/_2$ (portland)	1 to 1 $^1/_4$	Not more than 3 parts for each part of cementitious material

have been used successfully for many years. In making a comparison with the portland cement and lime and sand mixtures they should be evaluated on the basis of compressive strength and workability.

Table 11 gives six different sets of proportions for mortars. The first three correspond to the mixtures mentioned in the foregoing discussion. The two types identified by capital C are not recommended in locations where mortar is in contact with soil. Their use may be permitted in exterior and interior walls of solid masonry, in interior nonloadbearing walls or partitions of hollow units, and in other locations for which types A or B are not specifically required.*

Mortar of type D hardens very slowly and may soften if kept wet. It is not recommended for parapet walls, rubble-stone walls, or for uses where it will be in contact with soil. Where this type is used, lower limits should be set for height and spacing of lateral supports than for walls built with stronger mortars (see p. 27-48).

The only advantage of using either type C or type D would be economy, and the designer should carefully check the requirements of his building, as well as local code restrictions before making such a decision. In districts subject to earthquakes, proportions of the mortar ingredients are often definitely controlled. For example, many West Coast cities require that cement-lime motar be mixed in the volumetric proportions of 1 part portland cement : $^1/_2$ part lime putty : not more than 4 $^1/_2$ parts sand. Where a so-called cement mortar, corresponding to type A in the table, is required many codes in various parts of the country limit the permitted amount of lime to less than the maximum allowed by this standard. Such limitation is seldom justified but may be mandatory.

Table 12 gives the minimum compressive strengths which the mortars mixed in the corresponding proportions may be assumed to develop at an age of 28 days when tested in 2-in. cubes. Such tests should be performed as prescribed in the *Federal Specification for Masonry Cements* SS-C-181b (except for type D).

Table 12. Classification of Masonry Mortars on a Basis of Strength

(From *American Standard Building Code Requirements for Masonry*)

Type	Minimum Compressive Strength of 2-in. Cubes at 28 Days, psi
A	2500
B	600
C	200
D	75

Mortar Colors and Admixtures. Inorganic compounds that are free from acids or soluble salts, and of a type that will not react with calcium hydroxide, are used for coloring mortars. With the exception of carbon black and other colors of specific gravity less than 3.0, a quantity up to about 10% by weight of the cement may be used without harmful result.

Experience in the field and laboratory tests indicate that some mortars may be improved by incorporating proprietary compounds. Some of these diminish the absorption of surface water, others accelerate hydration, lower initial shrinkage of the mortar, or increase workability. No nationally accepted standards have as yet been promulgated for gaging the value of these materials. The designer will be guided in their selection by tests furnished by the manufacturers and by the history of their performance. Anti-freeze compounds of a proprietary type are not recommended. The use of salt for lowering the freezing point of mortar should be prohibited.

Solid Brick Masonry. Except for rare cases where porous brick have been used, the improper filling of the joints, particularly the vertical joints, is the usual cause of leakage. All brick should be laid upon an adequate thickness of mortar evenly spread over the horizontal bed. In order to make certain that the vertical joints are filled, brick should be laid with a full "shove-joint," or plenty of mortar should be "thrown" on the end of the brick to be placed, or on the end of the adjoining brick already laid, and the brick pushed into place so that the mortar oozes out at the top of the joint. The common practice of "slushing" vertical joints is not recommended. All exposed joints should be thoroughly compacted. The application of a $^1/_2$-in. mortar coat to the inner surface of an exterior vertical layer of brick, or to the outer surface of the backing material, forms a helpful water barrier. Mortar used in this manner and the operation of applying it are called "parging."

---

* This and the following paragraph have been adapted but not directly quoted from *American Standard Building Code Requirements for Masonry*, ASA A41-1-1944.

The allowable working stresses in solid brick masonry, corresponding to various mortar types and the strength of the brick, are given in Table 13.

Table 13. Compressive Stresses in Solid Brick Masonry

(From *American Standard Building Code Requirements for Masonry*)

Brick and other solid units of clay or shale, sand lime, or concrete brick.

Average Compressive Strength of Units Tested in the Position Taken in the Masonry, psi	Allowable Compressive Stresses Corresponding to Mortar Types, psi			
	A	B	C	D
8000 plus	400	300	200	100
4500 to 8000	250	200	150	100
2500 to 4500	175	140	110	75
1500 to 2500	125	100	75	50

The thickness and bonding of solid brick masonry walls should be checked upon requirements of the local building code, particularly in districts subject to earthquakes. As a guide to the designer, the following recommendations are abstracted from *American Standard Building Code Requirements for Masonry.*

Thickness: Solid Masonry Bearing Walls. (*a*) The thickness of solid masonry bearing walls shall be sufficient at all points to keep the combined stresses due to live, dead, and other loads for which the building is designed within the limits given in the preceding table.

(*b*) Except as otherwise provided in this section, the minimum nominal thickness of solid masonry bearing walls shall be 12 in. for the uppermost 35 ft of their height and shall be increased 4 in. for each successive 35 ft, or fraction thereof, measured downward from the top of the wall.

(*c*) Where solid masonry bearing walls are stiffened at distances not greater than 12 ft apart by cross walls, or by internal or external offsets or returns at least 2 ft deep, or by reinforced concrete floors, they may be of 12-in. nominal thickness for the uppermost 70 ft, measured downward from the top of the wall, and shall be increased 4 in. in thickness for each successive 70 ft or fraction thereof.

(*d*) In buildings not more than three stories in height, solid masonry bearing walls of the top story may be of 8-in. nominal thickness when the total height of the wall does not exceed 35 ft, provided that such 8-in. walls do not exceed 12 ft in height and that the roof beams are horizontal.

(*e*) In residential buildings not more than three stories in height, solid masonry bearing walls may be of 8-in. nominal thickness when not over 35 ft in height. Such walls in one-story single-family dwellings and one-story private garages may be of 6-in. nominal thickness when not over 9 ft in height, provided that when gable construction is used an additional 6 ft is permitted to the peak of the gable.

(*f*) Solid masonry walls above roof level, 12 ft or less in height, enclosing stairways, elevator shafts, penthouses, or bulkheads may be of 8-in. nominal thickness and may be considered as neither increasing the height nor requiring any increase in the thickness of the wall below, provided that the requirements for allowable stresses are met. Requirements for lateral support are as given on p. 27-48.

Thickness: Solid Masonry Nonbearing Walls. Nonbearing walls of solid masonry may be 4 in. less in thickness than required for bearing walls, but the nominal thickness shall be not less than 8 in., except where 6-in. walls are specifically permitted.

Bond. The facing and backing of solid masonry walls shall be bonded, either with at least one full header course in each seven courses, or with at least one full-length header in each 1.5 sq ft of wall surface. This distance between adjacent full-length headers shall not exceed 20 in. either vertically or horizontally. In solid brick walls of more than 8-in. nominal thickness, the inner joints of header courses shall be covered with another header course which shall break joints with the course below.

The more common methods of finishing the exposed surfaces of mortar joints are shown in Fig 22. The concave or rodded joint is the best. The second choice is the weathered joint. For standard work a $^{1}/_{2}$-in. joint thickness is usually satisfactory. If the principles of modular design are applied, the joint thickness will be fixed.

Solid Stone Masonry. The allowable working stresses in solid stone masonry, corresponding to various mortar types and various stones, are given in Table 14.

Table 14. Compressive Stresses in Solid Stone Masonry

(From *American Standard Building Code Requirements for Masonry*)

Material	Allowable Compressive Stresses, Corresponding to Mortar Types, psi			
	A	B	C	D
Granite, ashlar	800	640	500	400
Limestone, ashlar	500	400	325	250
Marble, ashlar	500	400	325	250
Sandstone, ashlar	400	320	250	160
Cast stone	400	320	250	160
Rubble stone	140	100	80	. . .

The recommended minimum thickness and bonding of solid masonry are given in the following abstract from *American Standard Building Code Requirements for Masonry.*

Thickness. (*a*) The thickness of stone walls shall be sufficient at all points to keep the combined stresses due to live, dead, and other loads for which the building is designed within the prescribed limits.

(*b*) The minimum thickness of walls of stone ashlar shall be not less than that required for solid masonry walls on p. 27-45.

(*c*) Rubble stone walls shall be 4 in. thicker than is required for solid masonry walls of the same respective heights, but in no case less than 16 in. thick. Requirements for lateral support are as given on p. 27-48.

Bond. (*a*) In ashlar masonry bond stones uniformly distributed shall be provided to the extent of not less than 10 per cent of the area.

(*b*) Rubble stone masonry 24 in. or less in thickness shall have bond stones with a maximum spacing of 3 ft vertically and horizontally, and if the masonry is of greater thickness than 24 in., shall have one bond stone for each 6 sq ft of wall surface on both sides.

In ashlar masonry, the thickness of both vertical and horizontal joints usually varies between $^1/_4$ and $^5/_{16}$ in. When the stone is laid the mortar is either kept back from the face or raked out to a depth of $^3/_4$ in. At some later period, the exterior joints are filled and finished to the required surface appearance. The more usual types are the same as those shown in Fig. 22.

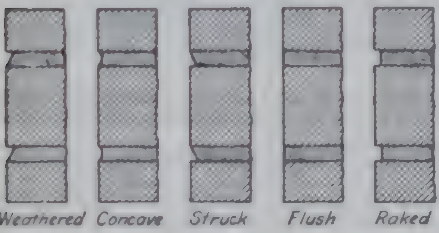


FIG. 22. Common types of exposed joints. (Reproduced by permission from Crane, *op. cit.*)

Walls of Hollow Masonry Units. This classification applies to walls built of structural-clay tile or hollow concrete-masonry units. These materials are widely used for back-up purposes with stone or brick facings. The joint thickness is usually $^3/_8$ in. Portland cement-stucco is normally applied when structural-clay or concrete-masonry units are used without other surfacing. An alternate finish applicable to the concrete-masonry is two coats of cement paint. Special concrete-masonry units are manufactured to serve as a wall-surfacing material and are laid in various patterns.

The allowable compressive stresses in pounds per square inch of gross cross-sectional area, for masonry of hollow units of structural-clay tile or of hollow concrete masonry, should not exceed 85 psi when laid in type A mortar or 70 psi when laid in type B mortar.* The following recommendations are abstracted from *American Standard Building Code Requirements for Masonry.*

Thickness and Height. (*a*) The thickness of walls of structural-clay tile or hollow concrete-masonry units shall be sufficient at all points to keep the combined stresses due to live, dead, and other loads for which the building is designed within the allowable stresses.

(*b*) The minimum thickness of walls of structural-clay tile or hollow concrete-masonry units shall be not less than that required for solid masonry walls, as given on p. 27-45.

(*c*) Walls of structural-clay tile or hollow concrete-masonry units shall not exceed 50 ft in height above the support of such walls. Requirements for lateral support are as given on p. 27-48.

Bond. (*a*) Hollow masonry units shall have full mortar coverage of the face shells in both the horizontal and vertical joints.

(*b*) Where two or more hollow units are used to make up the thickness of a wall, the stretcher courses shall be bonded at vertical intervals not exceeding 34 in. by lapping at least 3 $^3/_4$ in. over the unit below or by lapping with units at least 50 per cent greater in thickness than the units below at vertical intervals not exceeding 17 in.

(*c*) Where walls of hollow masonry units are decreased in thickness, a course of solid masonry shall be interposed between the wall below and the thinner wall above.

Structural Glass Block. The usual thickness is 3 $^7/_8$ in. with sizes 5 $^3/_4$ by 5 $^3/_4$, 7 $^3/_4$ by 7 $^3/_4$, and 11 $^3/_4$ by 11 $^3/_4$ in. Mortar bearing surfaces are often corrugated and coated with an alkali and moisture-resistant aggregate material to insure proper bond. Noncorrodible wire ties are placed in the joints. If panels are not set into chases they are anchored to adjoining walls with perforated metal strips. Panels greater than 144 sq ft in area, over 25 ft long, or 20 ft high should be divided horizontally by mullions or vertically by shelf angles. Glass block are usually laid in mortar of volumetric proportions; 1 part white portland cement : 1 part lime putty : 4 parts fine sand. Joints vary from $^3/_{16}$ to $^3/_8$ in. Expansion strips are used at jambs and heads of panels.

Faced and Veneered Walls.† Ashlar masonry of natural or cast stone, face brick, architectural terra cotta, structural glass, and occasionally other materials are used as a facing or as a veneer over a backing of cheaper masonry units. Figure 23 shows typical examples of brick facing over clay tile and concrete block. A "faced wall" is one in which the masonry facing and backing are bonded to act together under load; a veneered wall is one in which the masonry facing is not so bonded, being merely attached to the backing.

---

* Also quoted from *American Standard Building Code Requirements for Masonry*, ASA A41.1-1944.

† The requirements applying to masonry for faced walls have been adapted but not directly quoted from *American Standard Building Code Requirements for Masonry*, ASA A41.1-1944.

In conventional wall assemblies, the minimum thickness of the facing should be 2 $^1/_4$ in. or not less than one-eighth the height of the unit. The full cross section of both the facing and the backing is then included when computing the unit stresses, which should not exceed those allowed for the weaker of the two materials. The total structural thickness of faced walls should not be less than that required for masonry walls of either of the types forming the facing and backing. Brick facing should be bonded to the backing, as noted on p. 27-44 for solid brick masonry. Ashlar facing of either natural or cast stone should have at least 20% of the superficial wall area extending not less than 3 $^3/_4$ in. into the backing to form bond stones, which should be uniformly distributed throughout the wall. Substantial noncorrodible metal anchors, at least 0.2 sq. in. in cross section, should be required for every projecting stone, and, except when alternate courses are full bond courses, every stone not a bond stone should be similarly anchored. Each stone more than 2 ft in length and 30 sq ft in superficial area should have two anchors. Facing stones not over 12 sq ft in area should have at least one anchor to each 4 sq ft of superficial face area. The bond required between a backing of structural-clay tile or hollow concrete-masonry and a facing of hollow units is the same as described for walls of hollow masonry units.

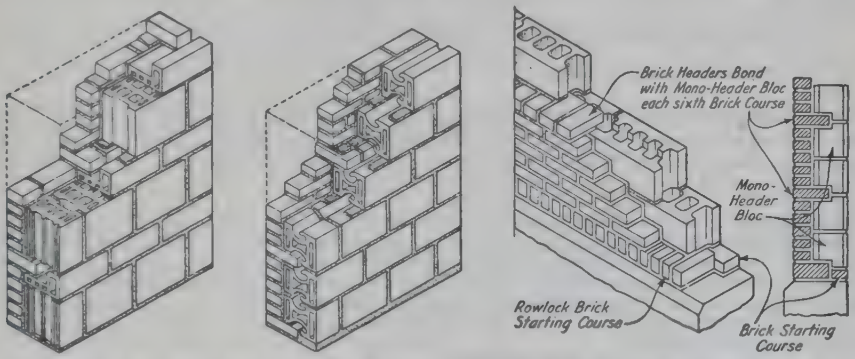

FIG. 23. Brick facing over tile and block backing. (Reproduced by permission from Crane, *op. cit.*)

Precast concrete panels 2 to 3 in. thick and ranging up to 8 by 10 ft in area may be used over concrete backing, poured-in-place, or over masonry. For concrete backing, the panels serve as exterior forms.

Precast concrete wall facings have a wide application to many classes of occupancy. They have been used for commercial and even monumental buildings (Ref. 6).

Concrete Walls Above Grade. Cast-in-place concrete may often be used to advantage for low structures. Such structures may be of panel, curtain, or bearing wall design. The minimum thickness for panel walls should be 4 in., increased as required by local building code or structural demands. They should be reinforced with small rods representing about $^2/_{10}$% of the cross-sectional area of the wall both horizontally and vertically, and recessed into the adjoining elements of the structural frame to obtain stability against wind pressure and a weathertight joint. When serving as curtain walls or bearing walls, additional reinforcement is often required. In these cases, the minimum thickness is usually 8 in. It is important that additional reinforcement be placed around all openings.

Concrete walls may be veneered with practically any surfacing material, and either precast ornament or designs poured monolithically may be used as embellishment. For industrial buildings a satisfactory finish may often be obtained by wetting the wall surface with a thin cement mortar and lightly grinding with silicon carbide or other abrasive. This treatment is appropriate for conditions that prevent removal of forms prior to hardening of the concrete. If the forms can be promptly removed, as soon as security permits, a somewhat better finish may be obtained by wetting and rubbing the surface with fine sand beneath a wood float. In any case, all honeycomb, holes left by form ties, or other imperfections should be remedied before any surface treatment is applied. Standard references on the subject of concrete are *Report of the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete*, obtainable from the Portland Cement Association, and Report of American Concrete Institute Committee 318, *Journal of the American Concrete Institute*, Sept. 1947.

Furring Masonry Walls. Between the body or backing of a masonry wall and the interior finish, an air space is often provided. This may be formed by tile furring block, a free-standing tile partition, or any of the other means shown in Fig. 24. In damp locations corrodible metal furring is obviously inferior to masonry furring. Gypsum tile is appropriate only where there is no probability of moisture. The purpose of furring is to provide a more or less dead air space that assists in preventing the direct passage of wind-driven rain and increases the resistance of the wall to the transmission of heat. A clear air space at least $^3/_4$ in. wide is desirable.

Exterior walls of solid masonry, including concrete, should ordinarily be furred for residential occupancy and often for commercial structures. In garages and factories, where there is plenty of ventilation and the heat loss is not an important factor, furring is often omitted.

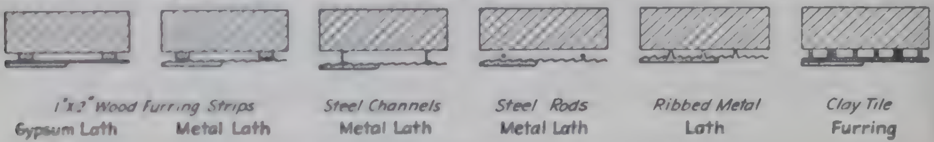

FIG. 24. Exterior masonry-wall furring. (Reproduced by permission from Crane, *op. cit.*)

Miscellaneous Structural Requirements. The following recommendations are quoted from *American Standard Building Code Requirements for Masonry*. They conform with the most modern practice in this field but are more liberal in some respects than those of many building codes.

Lateral Support. Solid masonry walls shall be supported at right angles to the wall face at intervals not exceeding 20 times the nominal wall thickness if laid in type A, B, or C mortar and not exceeding 12 times the nominal wall thickness if laid in type D mortar.

Walls of structural-clay tile or hollow concrete-masonry units and hollow walls of masonry shall be supported at right angles to the wall face at intervals not exceeding 18 times the nominal wall thickness.

Cavity walls shall be supported at right angles to the wall face at intervals not exceeding 14 times the nominal wall thickness.

Lateral support may be obtained by cross-walls, piers, or buttresses, when the limiting distance is measured horizontally, or by floors and roofs, when the limiting distance is measured vertically. Sufficient bonding or anchorage shall be provided between the walls and the supports to resist the assumed wind force, acting either inward or outward. Piers or buttresses relied upon for lateral support shall have sufficient strength and stability to transfer the wind force, acting in either direction to the ground. When walls are dependent upon floors or roofs for their lateral support, provision shall be made in the building to transfer the lateral forces to the ground.

Except for window-panel backs and permissible chases and recesses, walls shall not vary in thickness between their lateral supports. When a change in thickness, due to minimum thickness requirements, occurs between floor levels, the greater thickness shall be carried up to the higher floor level.

Bonding of Walls at Intersections. Masonry walls shall be securely anchored or bonded at points where they intersect and where they abut or adjoin the frame of a skeleton frame building. When two bearing walls meet or intersect and the courses are built up together, the intersections shall be bonded by laying in a true bond at least 50 per cent of the units at the intersection.

When the courses of meeting or intersecting bearing walls are carried up separately, the perpendicular joint shall be regularly toothed or blocked with 8-in. maximum offsets, and the joints provided with metal anchors having a minimum section of $\frac{1}{4}$ by $1\frac{1}{2}$ in. with ends bent up at least 2 in. or with cross-pins to form anchorage. Such anchors shall be at least 2 ft long, and the maximum spacing shall be 4 ft. Meeting or intersecting nonbearing walls shall be bonded or anchored to each other in an approved manner.

Anchoring of Walls. Masonry walls shall be securely anchored to each tier of wood joists or wood beams bearing on them at maximum intervals of 6 ft in one- and two-family dwellings, and 4 ft in other buildings, by metal anchors having a minimum cross-section of $\frac{1}{4}$ by $1\frac{1}{4}$ in. and at least 16 in. long, securely fastened to the joists or beams and provided with split and upset ends or other approved means for building into masonry. Girders shall be similarly anchored at their bearings. Anchors shall be attached in a manner to be self-releasing.

Masonry walls parallel to wood joists or wood beams shall be provided with similar anchors at maximum intervals of 8 ft in one- and two-family dwellings, and 6 ft in other buildings, engaging three joists or beams. Upset and T-ends on anchors shall develop the full strength of the anchor strap.

Cast-in-place concrete slabs bearing on masonry walls shall be considered as sufficient anchorage for the supporting walls.

Chases and Recesses. There shall be no chases in walls of less than 12-in. nominal thickness or within the required area of any pier, and no chase in any wall shall be deeper than one-third the wall thickness, except that in dwellings not over two stories in height vertical chases may be built in 8-in. walls under the following limitations: In 8-in. bearing walls the chases shall not exceed 4 in. in depth, 30 in. in width, and 2 ft in height, and shall not extend below the level of joist bearing, provided that where such chases occur below window sills the width may be not in excess of the width of the window opening above. In any case, not less than 4 in. of masonry shall remain between the back of chase and exterior surface of wall, and the backs and sides of all such chases in exterior walls shall be waterproofed and insulated. Masonry directly over chases wider than 12 in. shall be supported on lintels. Chases permitted in 8-in. walls shall not be cut but shall be built in as construction progresses.

No horizontal chase shall exceed 4 ft in length, nor shall the horizontal projection of any diagonal chase exceed 4 ft in length. There shall be at least 7 3/4 in. of masonry between chases and the jambs of openings.

Recesses for stairways or elevators may be left in walls, but in no case shall the walls at such points be reduced to less than 12 in. unless reinforced by additional piers or by columns or girders of steel, reinforced masonry, or concrete, securely anchored to the walls on each side of such recesses. Recesses for alcoves and similar purposes shall have not less than 8 in. of material at the back. Such recesses shall be not more than 8 ft in width and shall be arched over or spanned with lintels.

The aggregate area of recesses and chases in any wall shall not exceed one-quarter of the whole area of the face of the wall in any story. Chases and recesses shall not be cut in hollow walls, cavity walls, or walls of hollow masonry units, but when permitted may be built in.

Lintels and Arches. The masonry above openings shall be supported by arches or lintels of metal or masonry, plain or reinforced, which shall bear on the wall at each end for not less than 4 in. Stone or other nonreinforced-masonry lintels shall not be used unless supplemented on the inside of the wall with iron or steel lintels or with suitable masonry arches or reinforced-masonry lintels carrying the masonry backing.

Steel or reinforced-masonry lintels shall be of sufficient strength to carry the superimposed load without deflection of more than 1/360 of the clear span. Masonry arches shall have at least 1-in. rise for each foot of span and shall be designed to carry the superimposed load. Proper provision shall be made for resisting lateral thrust.

Separation of Combustible Structural Members. No wall of 8-in. nominal thickness shall be broken into, subsequent to building, for the insertion of structural members. A separation of at least 4 in. of solid masonry shall be provided between combustible members which may enter walls from opposite sides.

When unprotected steel or combustible structural members frame into hollow walls of thickness not greater than 12 in., they shall project not more than 4 in. into the wall and shall be spaced so that the distance between embedded ends is not less than 4 in. The space above, below, and between such members shall be filled solidly with burned-clay materials, mortar, concrete, or equivalent fire-resistive material to a depth of not less than 4 in. on all sides of the members.

All open cells in tiles or blocks occurring at wall ends shall be filled solidly with concrete for a depth of at least 6 in., or closure tiles set in the opposite direction shall be used.

Beam Supports. Beams, joists, girders, or other concentrated loads, supported by a wall or pier, shall have bearing at least 3 in. in length upon solid masonry not less than 4 in. thick or on a metal bearing plate of adequate design and dimensions to distribute safely the loads on the wall or pier.

Parapet Walls. Parapet walls shall be at least 8 in. in nominal thickness. They shall be not higher than 4 times their thickness unless laterally supported, provided that, when reinforced both horizontally and vertically with not less than 1/4-in. rods spaced not more than 2 ft on centers, the height shall be not more than six times the thickness. All parapet walls shall have a coping of incombustible material.

Piers. The unsupported height of piers shall not exceed 10 times their least dimension. When structural-clay tile or hollow concrete-masonry units are used for isolated piers to support beams and girders, the cellular spaces shall be filled solidly with concrete of type A mortar, and when so constructed the allowable stresses may be increased 25 per cent, provided that unfilled hollow piers may be used if their unsupported height is not more than 4 times their least dimension.

WALLS SURFACED WITH SHEET METAL. Specially formed sections of steel sheets have come into general use for the exterior wall surfaces of industrial buildings. These supplement corrugated iron, corrugated zinc, and sheet copper. An interesting design appropriate for industrial work is employed in a so-called windowless factory or, more correctly expressed, a controlled-conditions plant. Light and interior atmosphere are regulated to meet the requirements of the occupants. Objectionable sound is largely eliminated. The structural support of the wall and roof is steel. The masonry wall below sill level is of brick backed by Fiberglas board with an interior finish of clay tile. Above the sill, steel panels are used for the exterior finish. These are 30 in. wide, fabricated from 18-gage steel and ribbed 10 in. on centers. They are supported by girts or other framing on spans up to 12 ft. The shape of the panels, backed by the Fiberglas insulation board, results in the formation of vertical flues, which provide air circulation within the wall. A vapor seal is applied to the inner face of the board. Four-inch Fiberglas bats, compressed to 3 in. and covered by a 7-mm Fiberglas mat, retained in place with expanded metal lath, serve as insulation and interior finish. This particular combination of materials was designed to obtain low heat transmission, good sound absorption, and light reflection.

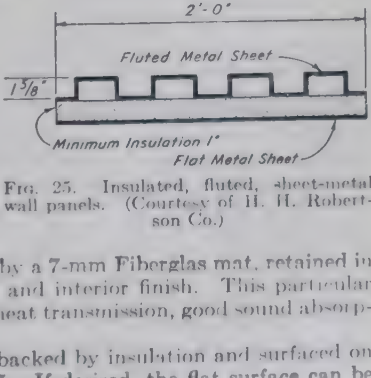

Fig. 25. Insulated, fluted, sheet-metal wall panels. (Courtesy of H. H. Robertson Co.)

A design employing fluted panels on the exterior, backed by insulation and surfaced on the inside with flat metal sheets, is shown in Fig. 25. If desired, the flat surface can be used on the exterior. The more recent installations made by the sponsors of this system employ aluminum sheets separated by an insulation of Fiberglas. The advantage of dry-wall construction, combined with speed in erection resulted in the wide acceptance of these metallic designs for industrial buildings during World War II. In addition to these purely utilitarian types, several of the more expensive metals are now furnished in practicable shapes to serve as exterior surfaces. Both aluminum and stainless steel are included in this category supplemented by various designs in porcelain-enameled iron or steel. In considering the appropriateness of any proposed design, the fire rating should be checked where it is important, as some assemblies unbacked by masonry are classed merely as incombustible.

GUNITE AND STUCCO SURFACES. Gunite. This is the trade name of a portland-cement-sand mixture combined with water when discharged in the form of mortar from the nozzle of a cement gun. The process has a broad application for remedial treatments applied over deteriorated concrete or masonry surfaces, but it may also be used advantageously as a means of constructing thin walls and partitions.

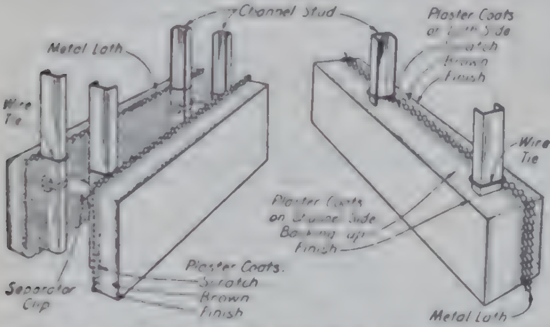

FIG. 26. Hollow and solid channel-stud partitions. (Courtesy of Metal Lath Manufacturing Assoc.)

Gunite may be shot against any solid backing such as a temporary wood panel or insulating board serving as a permanent part of the wall assembly. When insulation is not desired, the mortar may be shot against a backing of heavy paper with reinforcing mesh attached to a steel or wood frame. The same treatment may be used to form both an exterior and an interior surface, resulting in a hollow wall. The thickness of a solid section usually varies from 1 $^1/_2$ to 2 in., but may be made thicker when desired. The finished surface is of uniform, slightly rough texture.

Stucco Surfaces. The term *stucco* generally signifies cement-aggregate mortar applied by hand to form an exterior surface. Coloring is usually incorporated in the final coat. Plasticizing and waterproofing agents may be used. The material is applied directly to a masonry base or to welded-wire mesh attached to framed construction of steel or wood. When properly applied, portland-cement stucco is durable and impervious to wind-driven rain, but it is absolutely essential that good practice be followed in every detail and that differential movement be avoided between the exterior stucco and the structural assembly supporting it. Stucco is particularly vulnerable to even slight settlement of the supporting wall, steel or wood frame. If appreciable differential volumetric change occurs between the base over which the stucco is applied and the enclosing envelope of stucco, the surface will crack. The best recommendations now available are given in *Standard Specification for Portland Cement Stucco*, approved by the American Standards Association in 1946.

WALLS SURFACED WITH CEMENT-AGGREGATE PLANK AND COMPOSITION BOARDS. Cement-aggregate Plank. Lightweight concrete planking composed of portland cement combined with slag, slag products, hard-coal cinders, or similar materials is used as an exterior wall surfacing for industrial buildings. Thoroughly reinforced with welded, galvanized wire, tongued and grooved, it may offer an economical choice for the lighter types of wall construction. Planks are usually bolted or clipped to T bars or other appropriate structural shapes, spaced 6 to 8 ft on centers vertically or horizontally.

Cement-asbestos Boards. The corrugated cement-asbestos boards mentioned in Article 6 are also appropriate for wall surfacing over structural steel and occasionally over wood framing for certain types of industrial buildings. Sheets may be either plain or corrugated. A typical size is 3 ft 6 in. by 8 ft. Supports are required at a maximum spacing between 5 and 6 ft on centers. They are usually in the form of steel girts. One particular assembly is composed of $^3/_8$-in. corrugated sheets backed by 1-in. insulating boards, to which the interior surface is veneered. The design furnishes a lightweight section with good insulation. The better materials in this group are highly resistant to the attack of most acid fumes or gases, extreme temperature variations, and alternate wetting and drying. They are also fire resistant. Of a light gray color, cement-asbestos boards are usually left unpainted.

Cemesto Board. Identified on p. 27-37, these sheets, as used for wall construction, vary in thickness from 1 $^1/_8$ to 2 in. They have an application for some types of industrial work and are used in more or less prefabricated designs for small dwellings.

PARTITIONS. Clay tile, concrete-masonry units, and gypsum tile have been widely used in fire-resistant buildings. The 2-in. solid metal-lath and plaster partition has a particular application for large housing projects for which the reduced thickness has special significance in increasing the available floor area. The solid plaster partition may also be useful for enclosing office spaces within a manufacturing plant. Figure 26 shows the construction of steel-stud partitions, both of hollow and of solid type. In connection with these designs it should be noted that the horizontal elements placed at top and bottom of the partition assembly can be easily attached to a concrete floor or ceiling by means of steel nails. Such installations have been highly developed by the New York City Housing Authority but have an application for other types of work. Figure 27 shows a comparison of weights for the more popular partition types. Table 15 shows the minimum thicknesses recommended for nonbearing masonry partitions.

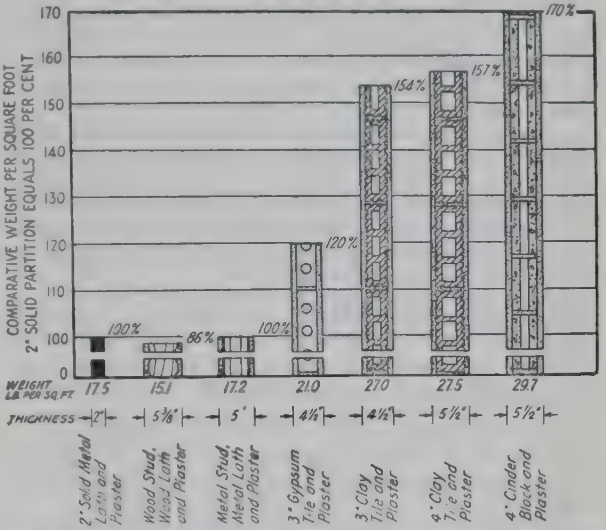

FIG. 27. Weights of various types of partitions. (Courtesy of Metal Lath Manufacturing Assoc.)

Table 15. Minimum Thickness of Nonbearing Masonry Partitions

(From *American Standard Building Code Requirements for Masonry*)

Maximum Unsupported Height, ft	Thickness Exclusive of Plaster, in.	Maximum Unsupported Height, ft	Thickness Exclusive of Plaster, in.
9 *	2	20	6
12	3	25	8
15	4		

* Not over 6 ft in length.

HEAT INSULATION AND VAPOR SEAL. These subjects as applying to roofs were discussed in Article 6. They are also important in relation to exterior walls for which insulation is often desirable to reduce the heat loss in cold weather or, more rarely, the heat gain in hot weather. Provision to avoid condensation on an interior surface of an exterior wall might require insulation, even when the heat loss could be accepted. Prevention of condensation of water vapor within an exterior wall assembly may require either a vapor seal on the warm side of the insulation or ventilation within the wall. This is particularly true if interior humidities are high.

Valuable information on this subject will be found in Accumulation of Moisture in Walls of Frame Construction during Winter Exposure, by Weber and Reichel, *Building Materials and Structures Report* BMS 93, National Bureau of Standards, 1942; Moisture Condensation in Building Walls, by Harold W. Wooley, also a Bureau of Standards publication, BMS 63, 1940; Comparative Resistance to Vapor Transmission of Various Building Materials, by L. V. Teesdale, *Journal of the American Society of Heating and Ventilating Engineers*, 1943; *Condensation in Walls and Attics*, by L. V. Teesdale, Forest Products Laboratory, Forest Service, United States Department of Agriculture, 1937.

FLASHING AND CAULKING. Locations Where Flashings Are Required. Flashings are generally necessary in the following locations:

(*a*) Wherever a parapet, chimney, or wall intersects a roof surface.

(*b*) Directly under the copings of parapets, chimneys, moat walls, and other masonry courses which form the top surface of exposed walls or piers, unless a continuous metallic coping is installed. Parapets, other than low parapets, should have an additional through-flashing, at the level of the cap flashing, or just above the flashing block (*c*) Either directly beneath or over masonry cornices and belt courses, for the purpose of preventing leakage through the vertical joints separating the masonry units forming the projection. The same statement applies to recesses.

(*d*) Usually across the top of basement walls to prevent moisture from traveling upward by capillary action. If metal is used for this purpose, it may be designed as a termite shield.

(*e*) Overall spandrel beams in skeleton construction at every floor and roof level, with particular care around columns.

(*f*) Generally at both heads and sills of all window, door, and other openings penetrating exterior walls. If sills are impervious to moisture and made in one piece, flashing may be unnecessary. If exterior stucco surfaces are used, flashings may be necessary along the sides as well as at heads and sills of openings. If stucco is placed over flashings, it should be carried by metal reinforcement thoroughly protected from corrosion.

(*g*) Except where eaves have a considerable overhang, between the top of the wall and lower surface of the roof.

In checking the flashings for a building, the designer would also give attention to the following locations, although they do not affect the structural work.

(*h*) Along the boundaries of flat roofs without parapets when surfaced with built-up waterproofing. In this case, the gravel stop may often be combined with a flashing which protects the eaves.

(*i*) On pitched roofs, all valleys are flashed. Hips and ridges are designed in conformity with common practice applying to the particular roof-surfacing material. Flashing is also necessary along horizontal lines where a change occurs in the slope of a pitched roof.

(*j*) Around all elements penetrating a roof surface, such as pipes or flues, in addition to the various wall locations previously mentioned. On comparatively flat roofs, the gutters and drainage connections are flashed into the surrounding waterproofing.

(*k*) Built-in gutters which require particular attention.

Excellent details illustrating good practice in the design of flashings may be obtained from the Copper and Brass Research Association.

The Choice of Flashing. The flashing material should be of a type suited to its particular exposure. As a guide to making a suitable choice, flashings may be divided, from the viewpoint of their appropriate uses, into the following groups.

Metals with Smooth Metallic Surfaces. Except where there is danger of staining with copper wash, soft-rolled 16- to 24-oz sheet copper is generally satisfactory. At least a 20-oz weight is recommended where permanence is a prime requisite. Zinc is also an acceptable flashing material but is more vulnerable than copper to certain types of atmospheric pollution. Both the 11-gage and 13-gage weights have been used. However, because of the particular characteristics of this metal, designs contemplating its use should follow the recommendations of the American Zinc Institute. When zinc is placed in contact with mortar containing lime, a heavy coating of paint or a bituminous compound free from acid is essential.

The lead and antimony alloy, generally called *hard lead*, can be used for flashings in weights of 2 to 3 lb per sq ft. Because hard lead has a high coefficient of thermal expansion and low elasticity, large sheets of it tend to "creep" and acquire a permanent set after wrinkles have developed. Designs should be checked with the Lead Industries Association. An asphaltum coating is recommended if lead is placed in contact with fresh mortar or concrete. Lead-coated copper is widely used for high-grade work in locations where copper staining would be objectionable or the color of copper inappropriate. There is also the general belief that the lead coating increases the permanence of the copper. This is generally true up to the point that the lead is worn through in spots. Beyond this stage, corrosion may be accelerated by electrolytic action. Aluminum also has possibilities as a flashing material but is not used to any extent for this purpose. As the coefficient of expansion due to temperature changes is very high aluminum should be used with caution. If brought in contact with mortar or concrete, it should be protected by a coating of lacquer to prevent corrosion.

As a class, the metallic flashings are appropriate for standard cap-and-base designs and for through-flashings. Galvanized steel sheets and the cheaper grades of tin plate should not be used except where their probable life will equal that of the roof-surfacing material. The choice should be based upon authentic records of performance under similar exposure or accelerated tests of a conclusive nature.

Thin Copper Sheets Surfaced with Bitumen-saturated Fabric. These sheets are very flexible as the copper is only 2- to 3-oz weight. They are particularly appropriate for spandrel waterproofing.

Membrane and Composition Flashings. Fabrics saturated with bitumen and laid in a bituminous waterproofing compound are appropriate for a dampcheck across the top of masonry walls and for spandrel waterproofing as an alternate to the material described in the preceding paragraphs. For this purpose two layers of fabric are laid with three coats of a cold-troweled mastic. Bituminous materials also serve as a cheaper but inferior substitute for the metal flashings of window sills and lintels. They are the usual choice for the junction of flat roofs surfaced with built-up waterproofing and parapets or penthouse walls.

Caulking. This term identifies the use of a plastic compound resembling putty instead of mortar for filling joints between masonry or other building units and for sealing the cracks around window frames and other wood or metal elements built into masonry walls. The material may be applied by extruding from a caulking gun, thereby forming a bead along the joint, or by the use of a trowel or knife. Consistencies suitable for either type of application are furnished by the manufacturers. Various colors are available. As certain types of caulking compounds have been found to stain porous materials, and considerable difference exists in both consistency and lasting quality, care should be exercised in choosing an appropriate material. Additional information on this subject will be found in Plastic Caulking Materials, by Tregoning, Milliken, Hockman, Sligh, and Kessler, *Building Materials and Structures Report* BMS 33, National Bureau of Standards, 1940.

DESIGN PROCEDURE. The problem is to select a wall construction which fulfills the desired functions at the least ultimate cost. The exterior finish should meet the utilitarian requirements of durability without costly upkeep. In some cases the appearance of the exterior and interior surfaces will be an important consideration. Interior surfaces should be suitable for the type of occupancy. The requirement that the wall be rain- and windproof is very important, but these qualities depend rather upon careful detailing, specification, and supervision than choice of the assembly.

In specifying the structural requirements of an exterior wall or partition, it is essential that the standards of a mandatory code or those dictated by good practice be constantly borne in mind. This is particularly important in districts subject to earthquakes.

Well-standardized methods have long been established for accommodating electric conduit, plumbing, and heating pipes within the outer surfaces of conventional wall assemblies, but when the newer prefabricated or semi-prefabricated designs are employed, the concealing or "building-in" of building elements should be carefully considered.

The outdoor-temperature range, solar intensity, and relative humidity for the various seasons may dictate the amount of heat insulation or favor one type of wall surface over another, as having a higher reflection of radiant heat or a greater time lag in heat transmission. When a particular manufacturing process causes or requires a high interior humidity, its possible effect should be considered.

The weights per square foot of the different wall assemblies are seldom important for low buildings, but should be considered for comparatively high structures, or in localities where a low soil-bearing capacity demands an appreciable increase in foundation cost to carry an increased dead load. The thickness of walls obviously affects the usable floor area. This condition is quite important in selecting partitions for multifamily dwellings, but it has little significance for industrial projects.

After these requirements are checked for each of the probable designs, preliminary estimates should be obtained for comparison. Only by using the material prices and labor rates applying to the time and place of construction, and with the local standard of man-hour production, can a valid estimate of cost be obtained. Unit prices in cents per square foot of wall area may sometimes serve as a general guide but are always unreliable and usually valueless for border-line cases.

8. CHOOSING THE TYPE OF FOUNDATION

The foundation of a building should transmit the weight of the superstructure, and any other loads, to an underlying stratum of soil or rock which is capable of furnishing support without objectionable settlement. The term *objectionable settlement* means an amount of settlement resulting in injury to the structure from either a utilitarian or an aesthetic viewpoint. All foundations, except those supported by sound rock, will settle somewhat. Slight, uniform settlement is of no importance for most buildings. Unequal settlement of the different parts of a structure, however, may cause serious stresses in the frame and cracks in floors and walls. A critical condition occurs where a portion of a building is supported on rock and the remainder on soil. This situation should be avoided, if practicable, by the use of concrete piers or piles carried down through the soil to a rock bearing. Where there is a probability of unequal settlement between two portions of a structure, vertical joints should be provided from top to bottom of the building.

Building records indicate that objectionable settlement is usually due to an incorrect evaluation of soil conditions rather than error in structural design. This condition indicates a need for adequate subsurface investigation. Information obtained in this manner may be supplemented by settlement records from other buildings, erected over similar soil conditions, soil loading tests made upon the site of the proposed building, and laboratory investigation of soil samples.

Foundations represent an appreciable portion of the building cost, and injury caused by settlement is expensive to repair. Although important advances have been made, particularly during the last generation, in the study of soil mechanics, this subject is at present far from an exact science. Because of the vastly different combinations of soils which may underlie a building foundation, both experience and good judgment, as well as a thorough knowledge of the rather extensive literature relating to this field, are necessary for important decisions regarding them. This section is consequently written to assist the building designer in correlating his procedure with the services of a foundation engineer, rather than to present a definite procedure for his own use.

SUBSURFACE MATERIALS. Types of Soil. Soil is the unconsolidated material formed by the disintegration of rock or organic substances. Sand and clay are the two principal classes. Sand is composed of comparatively large grains and clay of very small grains. Sand is often referred to as a cohesionless soil; clay as a cohesive soil. Sand is highly permeable to water; clay is comparatively impermeable. Sand is inelastic. Clay may have considerable elasticity, that is, ability to regain its original form and dimensions when an applied load, which has caused deformation, is released. Sand is not plastic, whereas clay has this characteristic, which means that it may change in shape without appreciable change in volume when subjected to continued loading.

The Boston Building Code gives the following definitions corresponding to the designations in Table 7.

Shale. A laminated, fine-textured soft rock composed of consolidated clay or silt, which cannot be moulded without the addition of water, but which can be reduced to a plastic condition by moderate grinding and mixing with water.

Slate. A dense, very fine-textured, soft rock which is readily split along cleavage planes into thin sheets and which cannot be reduced to a plastic condition by moderate grinding and mixing with water.

Schist. A fine-textured, laminated rock with a more or less wavy cleavage, containing mica or other flaky minerals.

Gravel. An uncemented mixture of mineral grains $\frac{1}{4}$ in. or more in diameter.

Sand. A type of soil possessing practically no cohesion when dry, and consisting of mineral grains smaller than $\frac{1}{4}$ in. in diameter.

Coarse Sand. A sand consisting chiefly of grains which will be retained on a 65-mesh sieve.

Fine Sand. A sand consisting chiefly of grains which will pass a 65-mesh sieve.

Compact Gravel, Compact Sand. Deposits requiring picking for removal and offering high resistance to penetration by excavating tools.

Loose Gravel, Loose Sand. Deposits readily removable by shoveling only.

Hardpan. A thoroughly compact mixture of clay, sand, gravel, and boulders, for example, boulder clay; or a cemented mixture of sand or of sand and gravel, with or without boulders, and difficult to remoke by picking.

Clay. A fine-grained, inorganic soil possessing sufficient cohesion when dry to form hard lumps which cannot readily be pulverized by the fingers.

Hard Clay. A clay requiring picking for removal, a fresh sample of which cannot be moulded in the fingers.

Medium Clay. A clay which can be removed by spading, a fresh sample of which can be moulded by a substantial pressure of the fingers.

Soft Clay. A clay which, when freshly sampled, can be moulded under relatively slight pressure of the fingers.

Rock Flour (Inorganic Silt). A fine-grained, inorganic soil consisting chiefly of grains which will pass a 200-mesh sieve, and possessing sufficient cohesion when dry to form lumps which can readily be pulverized with the fingers.

Ground Water. Below a certain level all soil is saturated with water. This level is often called the *water table*. It follows, approximately, the surface contours, but may be lowered by dry seams, by continued pumping, or by covering the ground surface with buildings or pavements. The ground water level has significance as affecting the bearing capacity of some soils, particularly fine sand and clay; as determining the level of "cut-off" for wood piles; and as causing increased cost of excavation and eventual provision for either waterproofing basements or the relief of water pressure by pumping.

SUBSURFACE EXPLORATION. Subsurface investigations should be made well in advance of the structural design. When there is a choice between two or more building sites, the result may determine the selection. Even where rock underlies the entire site of a future building, an investigation of its nature, by means of core borings, may be necessary. An illustration of a log of borings is published in *Bulletin* 208, Graduate School of Engineering, Harvard University.

For all important work "dry-sample" borings (see below) should be made as a preliminary step toward determining the most economical type of foundation assembly and as a guide in choosing the construction methods. In most cases this type of soil sampling gives sufficient data for design purposes, but over plastic soils such as clay, where the structural characteristics of the material, as well as the depth of the strata, may be in doubt, laboratory tests performed upon "undisturbed samples" (see p. 27-56) may be desirable.

The number of borings, or other type of soil exploration, obviously depends upon site conditions, the amount of supplementary information available, and the degree to which it seems necessary to develop a subsurface profile. In the general case, at least one boring should be made at points corresponding to the corners of the future structure. If soil conditions are variable, as they are particularly within glaciated regions, additional borings may be desirable. There is also a greater probability of encountering peat, organic or inorganic silt, and soft clay within glaciated regions. This area lies north of a line extending through Long Island, northern New Jersey, and Pennsylvania, along the Ohio and Missouri rivers into Kansas, thence northwesterly roughly parallel to and a little west of the Missouri River to the Rocky Mountains, thence westerly south of the Canadian border to the Pacific Coast.

At least one, and preferably several, of the borings should be carried down to a definitely determined stratum of rock or to a depth of not less than 1 $^1/_2$ times the width of the structure. For very wide buildings, where this depth appears excessive, judgment based on available information may warrant a lesser depth. If heavy loads are involved, the investigation of rock by means of core borings is often desirable, but the crushing strength of most rocks equals or exceeds that of the materials used for the substructure.

The records of foundation experience during construction and the subsequent settlement of adjacent structures, known to be supported by similar types of soil, often furnish valuable information. Geological advice is occasionally helpful. All available records should be checked to identify underground obstacles such as sewers, water and gas pipes, old foundations, and pier heads buried under fill.

METHODS EMPLOYED FOR SUBSURFACE EXPLORATION. **Test pits** are occasionally used where necessary to examine the soil in its natural state, but deep pits are costly as they generally require shoring and lining. Test pits, however, may offer an inexpensive means of making comparatively shallow investigations for small structures. For example, a pit may be dug to the level of the future footings, and a sample of soil obtained by means of an auger, or post-hole digger, from a depth 10 to 15 ft below that level.

Sounding rods are usually solid steel rods, or pipe sections, provided with points at the lower end. They are driven by hand or by a small gasoline-operated hammer. Provided that boulders or other obstacles are not mistaken for ledge rock, sounding rods may have a useful but limited application for determining the depth to rock, or other satisfactory bearings, such as gravel.

Auger borings are seldom used in building construction except for preliminary survey. The auger is rotated by hand or power. As the object is to raise samples of soil, its effective use is limited to cohesive materials, or noncohesive materials above ground-water level.

Wash-sample borings are obtained by driving a steel pipe casing, usually 2 or 2 $^1/_2$ in. in diameter, in 5-ft lengths by means of a hand-powered or power-driven drop hammer. Inside the casing, a 1-in. wash pipe, usually fitted at the lower end with a chopping bit, is churned up and down and rotated by hand to advance the hole.

A hand- or power-driven pump circulates the wash water down through the wash pipe and back to the surface through the annular space between the pipe and the casing. The water is then drained into a tub from which it is again recirculated. In its upward flow the water carries the loosened soil in suspension. As it is emptied into the comparatively still water of the tub, this material is partially deposited in the form of sediment. Samples of soil are then obtained by scraping a receptacle along the bottom of the tub. Such samples are referred to as "wash samples." As any individual sample may contain material from every stratum penetrated up to that time, and the finer particles of soil remain in suspension in the wash water, the results are of so little value that this method is not recommended.

Dry-sample Borings. This method employs the same procedure for drilling the hole as for wash-sample boring, but as soon as the foreman detects a change in the nature of the soil, as he turns the wash pipe at the end of the stroke, he raises the pipe off the bottom of the hole and continues pumping until the water flowing from the casing shows a substantial reduction in suspended soil.

The next step is to withdraw the wash pipe from the casing and substitute an open piece of 1-in. pipe, or a sampling spoon, for the chopping bit. The wash pipe is then returned to the hole and driven into the soil to obtain a sample. After the pipe is again withdrawn, the sample is removed and placed in a bottle. All samples are labeled with the number of the boring and the depth at which they were taken. After the chopping bit has been replaced on the end of the wash pipe, the operation is continued until another change of soil is encountered. As these samples have been removed ahead of the washing, they are identified as "dry samples" even if taken below ground-water level. This method of sampling has a broad application and in many cases furnishes adequate information for foundation design.

Undisturbed Sampling. In this method the same general procedure is followed up to the point that the soil specimens are taken. The object is to obtain a sample of soil with as little change in structure as possible. This type of investigation applies only to plastic soils, as the grains of granular soils suffer displacement in any known method of sampling. It is much more costly than dry sampling, but is used to procure specimens of soil for laboratory analysis. The usual tests that are performed are clearly described in Ref. 7.

Core borings are samples in the form of a more or less continuous core cut from rock. They are obtained by sinking a casing to refusal with earth-boring tools and tightly sealing it to the rock. Within the casing, an appropriate type of rotary drilling tool, such as a diamond or shot drill, is used to cut a core. It is not very large, often about 1 $^3/_8$ in. in diameter.

SPREAD FOUNDATIONS. The various types may be classified as wall footings, isolated or independent column and pier footings, combined footings, cantilever footings, continuous footings, and raft or mat and rigid-frame foundations. The surface or soil or rock upon which the foundation directly rests is called the *foundation bed*.

Wall Footings. Figure 28 shows the common designs employed for wall footings. Concrete is the most appropriate material wherever suitable aggregates can be obtained at a reasonable cost. A single rectangular section like the one shown in Fig. 28 (sketch *a*) is often sufficient to support basement walls of low, lightly loaded buildings. If plain concrete is used, the depth is made twice the projection from the face of the wall to prevent stresses that may rupture an unreinforced section. Even in footings of this type some longitudinal steel, such as the two rods shown in sketch *a*, may be desirable if there is any variation in the nature of the soil forming the foundation bed. If such is used, it should be placed 4 in. from the bottom and run continuously, with adequate splices, entirely around the building.

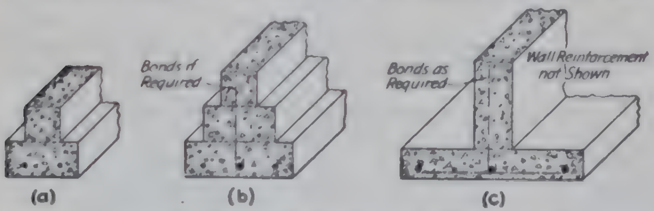

FIG. 28. Wall footings. (Reproduced by permission from Crane, *op. cit.*)

If the load per linear foot of footing, when divided by the allowable bearing value of the soil per square foot, results in a required projection of over 6 to 8 in., the single rectangular block shown in sketch *a* becomes too bulky. In such cases, another step may be introduced as shown in sketch *b*. This procedure of adding additional steps, each one of which has a depth of twice the projection from the wall, or superimposed block, could be carried on indefinitely. It is usually cheaper, however, if the total required width is more than about 3 ft, to use a laterally reinforced-concrete slab as shown in sketch *c*. When the stepped footing is used, adequate bond between the blocks should be obtained either by pouring the entire depth in a continuous operation, or otherwise effectively bonding the slabs comprising the footing.

Isolated or Independent Column or Pier Footings. Figure 29 shows various typical designs. The simplest type is of unreinforced concrete, as shown in Fig. 29, sketch *a*. This is appropriate beneath a wood post, lightly loaded pipe column, or similar compression member. A stepped footing may also be used under the same conditions for somewhat heavier loads. Both are also employed for concrete or masonry piers.

For other than very light loads, the designs shown in Fig. 29, sketches *b*, *c*, and *d*, are appropriate over either soil or piles. A square, rather than oblong plan, is desirable if space limitations permit. The choice between a single slab, sketch *b*, and a stepped design, sketch *c*, is merely one of economy. The single slab is wasteful of concrete; the stepped design is more costly to form. The area of the footing slab is located concentrically with the supported column or pier. A two-way reinforcement, placed 3 or 4 in. from the bottom of the slab, is customary; the ends of the rods should be hooked and protected by 3 or 4 in. of concrete. Pedestals are often used between the top of a footing and the base of the first tier of columns.

Beneath structural steel columns, a steel slab is normally employed, as shown in sketch *d*, to distribute the column loads. Beneath very heavily loaded columns, both a steel slab and a grillage, composed of I beams placed between the bottom of the steel slab and the top of the concrete footing, may be necessary for load distribution. Steel grillages enclosed in concrete are also used in place of reinforced-concrete slabs over a rock foundation bed. They are brought to level by means of grouting. In the past, such designs were employed over soil, but they are seldom found in present-day American practice. Various timber assemblies are hardly appropriate except for temporary structures, but they have been used for wood-framed buildings when placed beneath permanent ground-water level.

FIG. 29. Independent column footings. (Reproduced by permission from Crane, *op. cit.*)

Combined Footings. Exterior columns are often placed adjacent to property lines where space is not available for a concentric footing. Some method of overcoming the resulting eccentricity is necessary. The common solution is to combine the footing of the exterior column with that of the adjacent interior column. The shape of the combined footing is then determined so that the centroid of the area corresponds to the line of action of the resultant of the column loads. Figure 30, sketches *a*, *b*, and *c*, show typical designs. Sketch *a* is the more desirable plan as it is easier to design and construct than the plan shown in sketch *b*. However, space limitations may make the latter plan necessary. Sketch *c* shows a typical plan for a combined footing supporting four columns, a design that is often necessary at the corners of buildings where little or no projection is allowed beyond the faces of the columns on adjacent sides.

FIG. 30. Combined and cantilever footings. (Reproduced by permission from Crane, *op. cit.*)

Cantilever Footings. The design shown in Fig. 30, sketch *d*, is used to meet the same conditions as sketches *a* and *b*. Although this alternate is occasionally less expensive, it is not recommended for use except over piles adequately supported by point bearing.

Continuous Footings. A typical design is shown in Fig. 31. Although continuous footings may be used for the support of interior columns, they have their particular application for exterior columns when a foot or two is available between the exterior face of the column and the building line. Such a limited distance is generally insufficient to accommodate an isolated concentric footing, but may permit a continuous footing to be designed concentrically with the columns. Any of these designs may be used over either soil or piles with the exception previously noted for the cantilever footing.

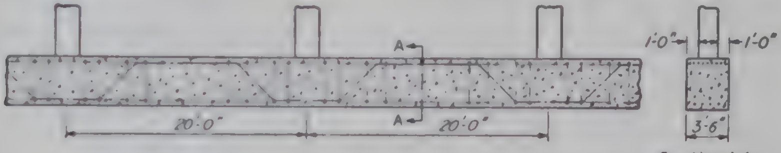

Fig. 31. Continuous footing. (Reproduced by permission from Crane, *op. cit.*)

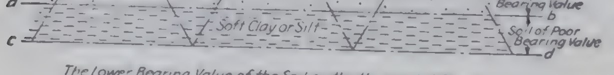
Raft or Mat and Rigid-frame Foundations. In their simplest form, the raft or mat foundation is an inverted slab of reinforced concrete, often several feet thick, which covers the entire basement area of a building. Such designs have apparently been an economical solution in some cases, but there is always the danger of excessive soil pressures occurring beneath heavily loaded columns. Furthermore, even if the design is made sufficiently rigid to distribute the loads over the soil between columns, a mat foundation may be uneconomical. This is because the load from individual column footings, at normal spacing, will often be spread over the entire basement area at a depth of less than 20 ft below the level of the foundation bed, and the increased area of the contact surface, consequently, may have no significance.

Rigid-frame designs are also occasionally used below grade to furnish a foundation assembly of sufficient rigidity to distribute the concentrated loads beneath columns. Such have their application over soils of low bearing capacity extending to a depth so great as to make the use of piles impracticable. One such rigid-frame design was used for the New England Mutual Life Insurance Company's building in Boston. Recent reports indicate that the design was a good solution for this particular project over the soil conditions existing at this site. Its success should not, however, lead to the unconsidered acceptance of such a design as normally safe and economical over all deep strata of low bearing capacity. Every building presents a special problem. Where conditions permit a foundation to be carried to rock bearing, it is structurally preferable to do so. This statement applies particularly to buildings of considerable height and to those of tower design.

BEARING CAPACITY OF SPREAD FOUNDATIONS. Table 7, p. 27-08, will serve as a general guide in cases where a local code does not enforce more restrictive requirements. Such bearing values, however, should be considered merely as maximums. Wherever there is any question of the quality of the material beneath the foundation bed, or its ability to support the proposed design without objectionable settlement, it should be checked by subsurface investigation, often supplemented by a soil-loading test.

Assumed Pressure Distribution beneath Footings. The soil-bearing values given in all building codes are commonly applied to the foundation bed which is the surface of the soil or rock immediately underlying the lower surface of the footing, or spread foundation. The transfer of load to underlying strata, even when the strata are of lower bearing value, is often neglected. This practice has so often resulted in excessive settlement that it is specifically mentioned in the following paragraph, also abstracted from the Boston Building Code.



The Lower Bearing Value of the Soil on the Horizontal Plane a-b must not be Exceeded when the Footing Load is Divided by the Area which, at this Level, is Bounded by the 60° planes The Bearing Capacity of Each Footing is Also Limited by the Product of the Area, Included Between the 60° Planes, and the Bearing Value of the Soil at the level c-d

Fig. 32. An assumption of pressure distribution beneath footings. (Building Code of Boston, Mass., 1944)

> Where the bearing materials directly under a foundation overlie a stratum having smaller allowable bearing values, these smaller values shall not be exceeded at the level of such stratum. Computation of the vertical pressure in the bearing materials at any depth below a foundation shall be made on the assumption that the load is spread uniformly at an angle of 60° with the horizontal, but the area considered as supporting the load shall not extend beyond the intersection of 60° planes of adjacent foundations.

Figure 32 shows the condition described in the preceding paragraph. Although the assumed distribution of pressure is only a crude approximation, and varies considerably for different types of soil, it should serve to direct the designer's attention to the danger of exceeding the safe bearing capacity of underlying strata that may be a considerable distance below an apparently satisfactory surface at the footing level.

Soil-loading Tests. There seems to be a common belief that an allowable soil-bearing value may be obtained by reducing the failure load, derived from small-scale loading tests, by a liberal factor of safety. This, however, is not a safe practice because the depth of pressure effect within the soil increases rapidly with the size of the loaded area. The settlement record derived from a small-scale test depends on the properties of a comparatively small volume of soil beneath the loading block or platform. The much deeper distribution of pressure beneath an entire group of footings, representing the complete foundation of a building, affects a much larger volume of soil. If the material is not uniform and homogeneous for a considerable depth, which, under some conditions, might approximate $1\frac{1}{2}$ times the width of the structure, little similarity may exist between the record of a loading test and the future settlement of a building. (See Refs. 8, 9, 10).

Furthermore, even if it can be established that soil conditions are homogeneous beneath the entire foundation bed, the pressure effect from adjacent footings will often overlap, thereby causing an excessive load upon some critical subsurface stratum. Increasing the size of the footings will obviously lessen the contact pressures on the foundation bed but may be of no value in relieving the pressure on a lower plane if, at that level, the load is already spread fairly uniformly over the entire available area. As pointed out by Prentis and White in their very practical book (Ref. 11), a foundation consisting of isolated spread footings would, under these conditions, be as efficient as a much more expensive mat or raft foundation placed over the entire basement area. This statement suggests choosing the footing areas, for any required column spacing, of just sufficient size to spread the load over the entire available subsurface stratum, which is considered to be the critical bearing medium.

It is suggested that bearing values derived from loading tests be studied in relation to all other available data such as the records of dry-sample borings, settlement records of other buildings erected over similar coil conditions and, as a last resort, in the case of cohesive soils, laboratory tests upon undisturbed samples.

The following requirements for a soil loading test are also taken from the Boston Building Code, 1944:

> (*a*) For bearing materials of classes 1 to 5 [see Table 7, p. 27-08], inclusive, the loaded area shall be at least 1 sq ft and for other classes at least 4 sq ft. For materials of classes 6 to 13 [see Table 7], inclusive, the loaded area shall be the full size of the pit and at such depth that the ratio of the width of the loaded area to its depth below the immediately adjacent ground surface is the same as the larger of the following two values:
>
> 1. Ratio of the width of any footing to its depth below the immediately adjacent ground surface.
> 2. Ratio of the width of the entire foundation or group of footings to its depth below the average surrounding ground surface.
>
> (*b*) When loading tests are made on bearing materials of classes 10 to 13, inclusive, suitable methods shall be used to prevent evaporation from the materials being tested.
>
> (*c*) A test load shall be applied which will produce a unit pressure equal to that for which the proposed foundations are designed. This load shall be allowed to remain undisturbed until no measurable settlement occurs during a period of 24 hours. The load shall then be doubled in increments not exceeding 25 per cent of the design load. At least 4 hours shall elapse between the application of successive increments. The total load shall be allowed to remain undisturbed until no measurable settlement occurs during a period of 24 hours.
>
> (*d*) Measurements of settlement shall be accurate to $\frac{1}{32}$ in. and shall be taken and recorded every hour during the first 6 hours after the application of each increment, and at least once every 12 hours thereafter.
>
> (*e*) When the design load upon bearing materials of classes 1 to 10, inclusive, causes settlement of less than $\frac{3}{8}$ in. and twice the design load causes settlement of less than 1 in., the design load shall be allowed; but if medium or soft clay underlies these materials, the vertical pressure in such clay shall not exceed that allowed in the table.
>
> (*f*) Whenever the proposed foundation rests on or is underlain by bearing materials of classes 11 to 13, inclusive, the results of loading tests must be interpreted in conjunction with accurate soil profiles showing magnitude and variation of the thickness of these strata. If this information, in the opinion of the commissioner, is not sufficient to determine whether the design load will cause excessive settlement, as might occur due to a thick stratum of clay, or dangerous differential settlement, as might occur when the underlying clay stratum varies considerably in thickness, the commissioner may require an analysis to be made of the probable magnitude, rate, and distribution of settlement of the proposed structure. Such analysis may be based upon:
>
> 1. A study of settlement records of near-by structures having essentially the same foundation conditions.
> 2. Consolidation tests and other investigations of undisturbed samples of the compressible materials.

TYPES OF PILES AND PILE DRIVING. Bearing piles are of the following types: wood piles; concrete piles, both precast and cast-in-place; structural-steel piles; metal-pipe piles; and composite piles, composed of wood or steel superimposed by concrete. All types are ordinarily driven in groups called clusters; a staggered arrangement of two or more parallel lines may be appropriate beneath bearing walls or continuous footings. Piles may also be distributed over an entire basement area beneath a reinforced concrete mat. The superimposed footings, known as pile caps, are similar in shape to those employed over soil.

Wood Piles. These are usually tree trunks driven with the small end down. In comparison with other types of piles, they are more appropriate for light than for heavy loads. Practically any kind of sound timber may be used.* For difficult driving a metal point may be employed. Lengths are determined to suit soil requirements. The diameter of the tip usually varies from 6 to 8 in. The diameter at the butt is seldom less than 12 in.; the taper should be uniform. For building foundations, untreated wood piles should be used only below permanent ground-water level. Except for temporary structures, even treated wood piles should be used with due consideration of the possibility of future replacement, when not entirely below ground-water level. This requirement alone may involve deep excavation with consequent expense for sheathing and pumping. In comparing the cost of wood piles with other types these items may be important.

If entirely embedded in soil and cut off below the lowest present or future ground-water level, or entirely submerged in fresh water, untreated timber piles may be considered permanent.† When exposed to unfavorable conditions, durability can be greatly increased by the use of coal-tar creosote impregnated by standard methods (Ref. 12). Either a treated or untreated pile, particularly the latter, may be injured by ground water containing alkali or acids. However, the principal danger to untreated timber piles is an unexpected lowering of the ground-water level, which causes the upper part of the pile to decay. Where there is even a remote possibility of this condition occurring in future years, the design should allow for such a contingency.

Concrete piles may be divided into two classifications, precast and cast-in-place. As they are immune to attack by biological organisms, they may be used where untreated wood piles would be inappropriate. If entirely embedded in soil, concrete piles may be considered permanent, whether above or below ground-water level, unless destructive acids, alkalies, or chemical salts are present.‡ Concrete piles extended above ground are subject to weathering and deleterious atmospheres to the same extent as concrete columns. Each type of concrete pile has its particular advantages and disadvantages in relation to soil conditions and the duty to be performed.

Precast Concrete Piles. Typical designs are square and octagonal. Circular sections are occasionally used. Although tapered designs are appropriate for the shorter lengths, up to about 40 ft, parallel sides and pointed ends are more usual. The parallel-side type has been cast with diameters up to 30 in. and in lengths over 100 ft.

The particular application of precast concrete piles is for conditions where the upper portion of the pile extends above the ground or water level, acting as a column for the superstructure. They are always reinforced internally to resist stresses caused by handling and driving. When serving as a column, or required to resist horizontal forces, additional reinforcement may be required. Pipes are occasionally placed in precast concrete piles to permit jetting while being driven. They are usually cast at the site of the future building.

Cast-in-place concrete piles are of two types: those in which a steel shell is left in the ground, and those which are shell-less or unencased. In the first type, the shell is usually of thin steel with a boot at the bottom. A heavy steel core, called a mandrel, is placed within the shell and carries it down when driven. The shell is uniformly tapered. When sufficient resistance has been obtained, the core is withdrawn, and the shell inspected by means of an electric light and filled with concrete. A standard design for the type just described has an 8-in. point diameter, the thickness increasing at the rate of 0.4 in. for each foot of pile length. As the practical limit of the uniformly tapered type is about

---

* Specifications of the American Society for Testing Materials and those of the American Railway Engineering Association.

† The statements in this article regarding the permanence of various types of piles follow the opinions expressed in Pile Foundations and Pile Structures, *Manual of Engineering Practice* 27, American Society of Civil Engineers, 1946. This manual, an excellent reference on the entire subject identified by the title, has been quoted in several portions of this chapter.

‡ This subject is treated very practically, with particular reference to concrete piles, in Pile Foundation, by A. E. Cummings, *Proceedings of the Purdue Conference on Soil Mechanics and Its Applications*, sponsored by the Society for the Promotion of Engineering Education, Purdue University, Lafayette, Indiana, 1940. Reprints are available from the Raymond Concrete Pile Company.

37 ft, a "step-taper" design has been developed which is driven in lengths up to nearly 100 ft. For greater lengths, a pipe-step-taper pile is available in lengths up to about 150 ft.

For the unencased type, a heavy steel shell or tube is used in combination with a steel core. After sufficient driving resistance has been obtained, the core is withdrawn and the tube filled with concrete. In this case, however, the core is then placed on top of the newly deposited concrete, at the upper end of the tube, and held in this position as the tube is pulled out of the ground. A modification of this procedure results in what is called a "pedestal pile." The pedestal is formed by ramming a portion of the concrete out of the lower end of the tube prior to complete withdrawal.

The cast-in-place pile, rather than the precast type, is the usual choice for ordinary building foundations. Installation is more rapid as no time is lost either in driving test piles, for the purpose of determining pile lengths, or in waiting for the piles to be cast and cured. Cast-in-place piles are not generally reinforced except where resistance to bending is required. Where soil conditions are favorable, the shell-less design may be more economical, but in many soils there is danger that subsurface pressures, or the driving of adjacent piles, will reduce or otherwise injure the concrete section.

Structural-steel piles are generally of rolled-steel H sections, designed with wide flanges. Their greater strength makes them appropriate for driving through dense gravel, or similar types of soil which would be difficult to penetrate with either wood or precast concrete piles. Their smaller cross section causes less compaction of the soil and, when driven in cohesive soils, less swelling of the ground. They are particularly suitable for deep driving where it is necessary to extend the foundation to rock. Lengths up to 120 ft have been successfully driven beneath the John Hancock Mutual Life Insurance Company's building in Boston, Massachusetts (Ref. 13).

If entirely embedded in comparatively impervious soil, steel piles may be considered permanent. When extended above the ground, there is the probability of rusting at the surface and for a short distance below grade. To avoid this danger the steel piles may be encased in concrete or coated with coal tar, extending from 6 in. above grade to 2 ft or more below the surface. If corrosive materials are present in the soil or ground water, such protection should be carried to a greater depth. When there are coal pockets, alkali soil, cinder fills of comparatively recent deposit, or waste from certain manufacturing plants in the immediate locality, the soil should be analyzed.

Metal Pipe Piles. Heavy, open-end cylindrical shells are the common type. Diameters usually range from 10 to 18 in. Shell thickness normally varies from $^{1}/_{4}$ to $^{1}/_{2}$ in.; a $^{7}/_{8}$-in. thickness has been used for 12-in. pipe where it was necessary to drive through obstructions. As in the case of the structural-steel piles, this type is normally driven to rock and can be designed to carry up to 150 tons. Lengths up to 100 ft have been used. When driven with a hammer, which is the usual procedure except when working beneath a structure, sections are sunk in lengths of about 20 ft. After driving, the soil contained within the pipe is blown out by means of compressed air and the pipe filled with concrete.

Composite piles may be of two types. In both cases the upper portion is of concrete superimposed upon either wood or steel. The wood and concrete combination is more common. The wood portion is designed of such length as to be always below groundwater level. The concrete portion is usually cast-in-place but may be precast. A typical composite pile comprises a cast-in-place step-taper pile above a wood pile. The advantage of such a combination is the comparatively low cost of the wood pile and the elimination of deep excavation which would be required if only wood were used and the cut-off elevation dropped below permanent water level.

Means by Which Piles Support Load. The two terms ordinarily used to identify the load that can be sustained by a pile foundation, without objectionable settlement, are *allowable safe load* and *bearing capacity*. A very important consideration is the bearing capacity of the subsoil strata underlying the points of the piles, as these strata must support the load placed upon the piles, in addition to the weight of the soil above this level, supplemented by any other imposed loads.

Piles may transfer their loads by point bearing to an underlying stratum, or by skin friction to the mass of soil in which they are embedded. Piles frequently furnish support by a combination of these two means, but all types may be roughly classified as either *end-bearing* or *friction* piles, depending on the means by which they obtain their chief resistance. In either case, however, the load is eventually imposed upon the material around and beneath the points of the piles.

Sketch *a* of Fig. 33 illustrates an end-bearing pile where practically all load is transmitted by point bearing to rock or other very hard stratum upon which it rests. The pile acts as a column with an indefinite amount of lateral support furnished by the material through which it is driven. Such piles must be strong enough to support the design load without injury to the tip. Sketch *b* illustrates a pile embedded in a firm stratum, such as dense sand or gravel, without clay or other soft strata below. Such a pile supports its load by friction through the lower portion, aided by end bearing. As the load in this case is transferred to the sand at the level of the pile points, the bearing capacity of such a stratum would limit the bearing capacity of the pile for any particular spacing.

Sketch *c* illustrates a similar condition, except that a stratum of soft clay, or other material of a low bearing capacity, is assumed to exist beneath the stratum of sand or gravel. In this case, the surface of the clay is the critical bearing area, and such a condition warrants very careful investigation. The load from a single pile, or even that of one cluster, may be distributed over a sufficient area to cause only slight settlement when a loading test is applied. When the entire foundation is in place, however, the overlapping of pressures from adjacent clusters may result in placing an excessive load upon the soft clay and cause serious settlement. Piles transmitting their load to any deposit of compressible material should be spaced so that the load-carrying capacity of the selected bearing stratum, and any underlying strata to a depth of not less than 1 $^1/_2$ times the width of the entire foundation, is not exceeded. This consideration may require limiting the load upon critical subsurface strata to that imposed by the original overburden.

Sketch *d* illustrates the case where piles are supported by friction throughout their full length. When embedded in silt, or soft clay, such an assembly is often referred to as a *floating* pile foundation. The segment of soil surrounding a pile, to which the load is transmitted, is known as the *bearing body*. For an entire pile cluster the same term is applied to the mass of soil lying within the perimeter of the group and closely surrounding it. As in the preceding case, the load-carrying capacity may be limited by the bearing value of the undisturbed soil beneath the level of the pile points. Where a compressible stratum lies below, a common type of failure is the general downward displacement of the bodies of soil around the pile clusters.

The bond between soil and pile, generally referred to as *skin friction*, is also important as a gage of the pile's resistance against slipping through the surrounding material. The value of the ultimate shearing stress in the soil is a measure of the tangential resistance which the earth can transmit. Sketch *e* shows piles driven their entire length into a stratum of loose sand and having the primary function of consolidating the material by vibration and lateral displacement. When such piles are driven in sufficient number and at proper spacing, the result is to form a more or less solid block bounded approximately by the perimeter of the pile cluster. Provided that there is no underlying stratum of lower bearing value, the bearing capacity of such a design is limited by the adequacy of the loose sand below the pile points to support the entire bearing body of consolidated sand.

Pile Driving. The selection of suitable pile-driving equipment is extremely important. It should be selected by a competent engineer who is familiar with the soil conditions and probable pile loads.

A drop hammer is essentially a heavy metal weight, raised by a hoisting line and allowed to fall on top of the pile by gravity. A single-acting steam hammer is a freely falling weight with steam pressure applied only to the underside of the piston for the purpose of raising the ram. In the double-acting steam hammer, the ram is likewise raised by steam. At the top of the stroke, however, steam is admitted to the upper side of the piston, and its pressure, added to the weight of the ram, increases the driving force. Piles are occasionally sunk by means of hydraulic jacks. Placed on top of a short pile, they force it down with resistance against the superstructure of a building, a temporary rig, or previously driven piles.

A water jet is often used when necessary to penetrate a considerable depth of sand or gravel. Jetting, however, should be used with discretion as there is danger of loosening adjoining piles; and if support is furnished by skin friction, the bearing value may be lessened by the soil's not settling back into place after driving. When piles are driven through soft clay, or silt, to a firmer material, such as coarse sand or gravel, it is important to obtain sufficient penetration in the firmer soil, and driving should often be continued even after adequate resistance has apparently been reached. The compression of the soil due to driving may raise piles already in place to such an extent that they no longer bear properly. If this condition is suspected, the levels of all pile heads should be checked after each cluster is complete. Those that have risen appreciably should be redriven.

Formulas for Computing Bearing Capacity. Although the limitation of data obtained solely by driving records is clearly apparent, dynamic formulas have been used for many years and with comparative success when they have been applied with discretion. For additional information on this subject see Pile Foundations and Pile Structures, *Manual of Engineering Practice* 27, American Society of Civil Engineers, 1946.

Engineering News *—drop hammers: $R = \dfrac{2Wh}{s + 1.0}$

Engineering News—single-acting steam hammers: $R = \dfrac{2Wh}{s + 0.1}$

Modified Engineering News formula: $R = \dfrac{2Wh}{s + 0.1P/W}$

Hiley formula (simplified) for drop hammers: $R = \dfrac{3Wh}{s + k} \times \dfrac{W}{W + P}$

Hiley formula (simplified) for single-acting steam hammers; $R = \dfrac{3.6Wh}{s + k} \times \dfrac{W}{W + P}$

where R = allowable safe static load on pile, pounds; W = weight of a drop hammer or striking parts of a single-acting steam or air hammer, pounds; P = weight of pile as driven, pounds; h = height of fall of a drop hammer or length of stroke of a steam or air hammer, feet; s = penetration of pile per blow, inches (either the last blow or the average of the last few blows); k = half the total rebound of pile hammer used in Hiley formula and expressed in inches.

These references will be found particularly helpful in connection with the application of pile-driving formulas:

Pile-Driving Handbook, by Robert D. Chellis, Pitman Publishing Corporation, 1944.

Dynamic Pile-Driving Formulas, by A. E. Cummings, *Journal of the Boston Society of Civil Engineers*, January 1940.

CONCRETE PIERS. Concrete piers are used to carry column loads through a material of low bearing value down to rock, hardpan, or gravel. Provided that the bearing capacity of the rock or soil is adequate, the design of a plain or reinforced-concrete pier does not present the many uncertain factors that enter into the design of spread foundations and piles. During the last thirty or forty years, methods of field construction have been highly developed, but their detailed description is not within the scope of this book.

The first problem involved is to choose the most economical method of sinking a shaft of the desired dimensions to the chosen bearing stratum. In building construction, this is often accomplished by means of open wells unless a considerable depth must be penetrated below ground-water level where soil conditions necessitate using pneumatic caissons. The system used for either full-lot or open-well excavation depends on the nature of the soil, the estimated amount of ground water, the required depth, and the necessity of avoiding injury to adjacent structures, as well as other considerations pertaining to the individual operation. For both full-lot excavation and individual pier foundations, steel sheet piling has a broad application. It may often be used in connection with perforated pipes, called *well points*. Such installations have permitted lowering the ground-water level as much as 30 ft.

A system known as the Chicago method, because of its particular use in that city, is applicable to open-well excavation where soil conditions are favorable. The open wells are dug beneath each column location. After the earth has been excavated to a depth of 3 to 6 ft, depending on the stability of the soil, the pits are sheathed with boards held in place by metal rings. The procedure of excavation and subsequent sheathing is then repeated, increasing the depth of the well, until the required level is reached. Piling of considerable length is used when it is necessary to excavate through water-bearing strata. In such cases, the tips of the piles, or other sheathing, may be sunk into clay, thereby sealing the bottom of the shaft and permitting practically dry excavation through a water-bearing stratum. In some types of soil both wood cylinders and open steel shells have been sunk by jacking.

---

* For a discussion of these and other pile formulas, see *Proc. Am. Soc. Civil Engrs.*, May 1941 and Sept. 1941.

The Gow caisson, composed of telescoping steel cylinders, power-driven successively and withdrawn in reverse order after filling with concrete, has its particular application for concrete piers supported by rock or soil of suitable bearing capacity, lying at moderate depths below grade or below an open excavation.

ILLUMINATION

By Samuel G. Hibben

9. LIGHT—CHARACTERISTICS AND MEASUREMENTS

THE RADIATION SPECTRUM. Light is that form of radiant energy which is capable of producing the sensation of sight. Visible energy is an exceedingly small portion of the *electromagnetic spectrum*, a tremendous range of radiant energy which travels through space in the form of electromagnetic waves. All these radiations are similar in nature and in the speed at which they travel (186,300 miles per second). They differ only in wavelength and frequency, and in the ways in which they manifest themselves. The present known spectrum ranges from cosmic rays with a wavelength of 1×10^{-15} cm, and a frequency of 3×10^{25} cycles per second, to 60-cycle a-c waves 3100 miles long (see Fig. 1).

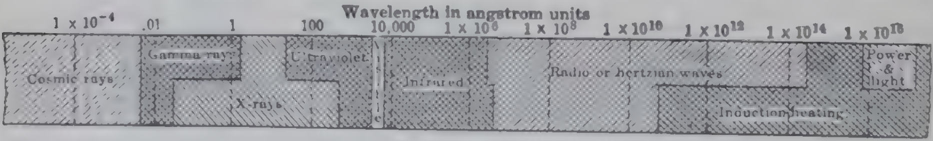

Fig. 1. Electromagnetic spectrum.

500-Watt daylight incandescent lamp	4000
White fluorescent lamp	3500
Photoflood lamp	3415
General-service incandescent lamps	2500 to 3050
Candle flame	1800

Table 2. Terminology and Measurement of Light and Illumination

Quantity	Symbol	Unit	Definition	Fundamental Equations	Method of Measurement	Principal Use
Luminous Intensity (Candlepower) Light density in a specified direction	I One "Hefner" equals 0.9 cp	Candle (c) The luminous intensity of a source expressed in candles is its candlepower (cp)	The standard unit of luminous intensity in a given direction is the *international candle.* An ordinary wax candle has a luminous intensity in a horizontal direction of approximately one candle. The international candle is the basic quantity in all measurements of light. Candlepower is always a property of a source of light, and gives information regarding luminous flux at its origin.	$CP = \text{Foot-candles} \times D^2$ (D = Distance in feet from source to illuminated surface). See Illumination. $MSCP = \frac{\text{Lumens}}{12.57}$ (Meanspherical candlepower is the average candlepower of a source in all directions.)	Candlepower measurements are primarily a laboratory procedure requiring special instruments. Rough estimates of the candlepower of a source or fixture can be made in the field by (1) holding a light meter at a distance of at least five times the greatest dimension of the source; (2) aiming the cell of the meter directly at the source; and (3) multiplying the foot-candle reading by the square of the distance in feet. (See Fundamental Equations.) There must of course be no other light in the room, and it may be necessary to make allowance for light reflected from walls and ceilings.	Candlepower is used not only to indicate the luminous intensity of a source in one particular direction; candlepower measurements are often taken at various angles around a source or a fixture, and the results plotted to give a *candlepower distribution curve.* Such a curve shows luminous intensity in any direction, and from it illumination calculations can be made.
Luminous Flux Time rate of flow of light Light is actually a form of radiant energy in motion. In common practice, however, the time element is neglected, and luminous flux is considered as a definite quantity.	F	Lumen (lm)	A lumen is the light flux falling on a surface one square foot in area, every point on which is one foot from a uniform point source of one candle. (Such a surface is a one-foot-square section of a sphere of one-foot radius, with a one-candle source at its center.) The lumen differs from the candle in that it is a measure of light flux *irrespective of direction.*	Lumens incident on a surface = Foot-candles × Area (sq ft) Lumens emitted or reflected by a surface = Foot-Lamberts × Area (sq ft) Lumens = MSCP × 12.57 (Since a sphere of one-foot radius has a surface area of 4π (12.57) square feet, a uniform point source of one candle must produce 12.57 lumens. The same relationship exists between the mean spherical candlepower of any source and its total lumen output.)	Lumen measurements of light sources are a laboratory procedure requiring special equipment. The lumens falling upon a surface may, however, be estimated with the aid of an ordinary light meter. First obtain foot-candle readings at various points on the surface in order to arrive at an average value; then multiply the average foot-candles by the area of the surface in square feet. (See Basic Formulas in Article 13.)	The lumen is used primarily to express the total output of a light source. It can also be used to indicate amount of light absorbed, transmitted, or reflected. The Lumen Method of calculating illumination provides average foot-candle values by the use of relatively simple formulas.

(*Table continued on p. 27-66*)

Table 2. Terminology and Measurement of Light and Illumination *Continued*

Quantity	Symbol	Unit	Definition	Fundamental Equations	Method of Measurement	Principal Use
Illumination Density of luminous flux on a surface Luminous flux may be called the *cause*, and illumination the *effect* or result. Usually the target visibility is the result of the light it reflects, rather than being measured by what falls upon it.	E	Foot-candle (ft-c) The unit, lux, is one lumen per square meter, so one foot-candle = 10.76 lux.	A foot-candle is the illumination at a point (A) on a surface that is one foot from and perpendicular to a uniform point source of one candle.  From the definition of a lumen it is obvious that one lumen uniformly distributed over one square foot of surface produces an illumination of one foot-candle.	Inverse Square Law Illumination decreases inversely as the square of the distance.  1 ft-c ¼ ft-c ⅑ ft-c Point source 1 candle 1 ft 2 ft 3 ft When light rays are perpendicular to the surface, the inverse square law as stated above applies:  $E = \frac{I}{D^2}$ E = Foot-candles I = Candlepower D = Distance in feet When light rays are not perpendicular to the surface:  $E_h = \frac{I \times \cos\theta}{D^2}$  $E_v = \frac{I \times \sin\theta}{D^2}$ Foot-candles incident on a surface = $\frac{\text{Lumens}}{\text{Area (sq ft)}}$	Various models of direct-reading photoelectric cell foot-candle meters and visual photometers are available. A discussion of these instruments and their use is found in the technical literature. The principle is to generate small electric currents through the action of light on selenium-copper oxide surfaces.	Foot-candle readings are used to indicate the illumination at a specific point, or the average illumination on a surface. The inverse square law is the basis of calculation in the Point-By-Point Method of lighting design. The inverse square law applies strictly only to a *point source*. With most types of interior-lighting fixtures, however, it is safe to assume that the law operates with sufficient accuracy for all practical purposes if the distance at which the measurements are taken is at least five times the greatest dimension of the light source. For special considerations involving linear sources note that the estimates of useful lumens are more useful than calculated foot-candles.

Brightness Luminous intensity in a given direction per unit of (projected) area A surface or an object has *brightness* by reason of light emitted, reflected, or transmitted. Brightness is ordinarily independent of distance of observation.	B or B^1	Candle per square inch (c in.^{2}) or Foot-Lambert (ft-L)	Brightness is expressed in two ways: in *candles* per unit area or in *lumens* per unit area. A surface emitting or reflecting light in a given direction at the rate of one candle per square inch of projected area has a brightness in that direction of *one candle per square inch.* A surface which has a brightness equal to the uniform brightness of a perfectly diffusing surface emitting or reflecting one lumen per square foot has a brightness of *one foot-Lambert.* The foot-Lambert is also the average brightness of any surface emitting or reflecting light at the rate of one lumen per square foot. A *lambert* is the brightness of a surface emitting or reflecting one lumen per square centimeter; a *millilambert* is one-thousandth of a lambert.	Ft-L = Foot-candles × Reflection factor of surface $\text{Ft-L} = \dfrac{\left\{\begin{array}{c}\text{Lumens (incident)} \times \\ \text{Reflection factor}\end{array}\right\}}{\text{Area (sq ft) of surface}}$ 1 candle per sq in. = 452 foot-Lamberts If the surface under consideration departs widely from the properties of a perfect diffuser, the lumens emitted or reflected cannot safely be calculated on the basis of a single brightness reading taken from any one angle. 1 lambert = 929 foot-Lamberts = 2.054 candles per sq in. 1 millilambert = 0.929 foot-Lambert = 0.002 candle per sq in.	Methods of making brightness measurements and the meters used for the purpose are described in Table 3. Real or apparent brightness of a source is candlepower divided by the projected area in that direction, i.e., the intrinsic brightness.	Relatively high brightnesses, such as those of light sources, are usually expressed in terms of candles per square inch. Since the average brightness of a surface in foot-Lamberts can be calculated by multiplying the illumination in foot-candles by the reflection factor, the foot-Lambert is a very convenient unit in which to express the brightnesses of illuminated surfaces.

Table 3. Reflection, Transmission, Refraction, and Polarization

Type of Control	Illustration	Unit	Method of Measurement	Instrument	Materials		Use
Reflection When a ray of light striking a surface is turned back, it is said to be *reflected*. Reflection may be of several types, the most common of which are *specular* (regular), *diffuse*, *spread*, and *mixed*.	 Specular reflection Diffuse reflection Spread reflection Mixed reflection	Reflection Factor The ratio of the light reflected from a surface to that incident upon it. The reflection factor of a given surface may vary considerably according to the direction and nature of the incident light. Specular reflection increases with angle of incidence, almost total reflection being obtainable at grazing angles. With colored surfaces the reflection factor may be quite different for different colors of light.	Place light meter cell against surface. Withdraw meter from surface slowly until constant reading is obtained (2 to 6 in.) (A). Place meter against surface with cell facing out (B) and note reading. Reflection factor = $\frac{\text{Reading }(A)}{\text{Reading }(B)}$	 	Reflecting Surface Magnesium Carbonate Polished silver White plaster Mirrored glass Alzak aluminum White blotting paper Porcelain enamel White paint Polished chromium Polished aluminum Polished nickel Aluminum paint Black paint	Per Cent Light Reflected 97–98 90 85–90 80–90 80–85 80–85 77–82 75–85 65 60–70 65 50–75 3–5	In *specular*, or *regular*, reflection, mirrors, highly polished metals the angle of incidence is equal to the angle of reflection (see Illustration: Angle X = Angle Y). In *diffuse reflection*, matte surfaces like white blotting paper, fresh snow, the maximum intensity is perpendicular to the surface, regardless of the angle of the incident beam. *Spread* reflection, as in sanded glass, is intermediate between specular and diffuse. Diffusing surfaces with a glazed superficial coat, like porcelain enamel, exhibit *mixed* reflection, a combination of specular and diffuse.
Transmission Light rays passing through transparent or translucent materials are said to be *transmitted*. The degree of diffusion of the transmitted light depends on the type and density of the material.	 Clear glass Diffusing glass	Transmission Factor The ratio of the light transmitted by a material to that incident upon it. Transmission depends to some extent upon the direction and quality of the light.	Place material to be tested over cell of light meter. Note reading (A). Remove material. Note reading (B). Transmission factor = $\frac{\text{Reading }(A)}{\text{Reading }(B)}$		Type of Glass Clear Frosted Figured or Ribbed Crystal Light-Density Diffusing Heavy-Density Diffusing	Per Cent Light Transmitted 80–90 75–85 70–85 55–70 10–45	In *regular* transmission (clear glass and plastics) the direction of the incident light is not changed. Diffusing media, such as dense opal glass, scatter the transmitted light so that its maximum intensity is normal to the surface. As in reflection, between the two extremes of regular transmission and perfectly diffuse transmission are to be found all degrees of diffusion.

Refraction A light ray bent by passing obliquely from one transparent medium to another in which its velocity is different (as from air into glass) is said to be *refracted*.		Index of Refraction The ratio of the speed of light in free space to the speed of light in the medium in question. $V = \frac{\text{vel. (air)}}{\text{vel. (medium)}}$	By special laboratory apparatus only.	Index of refraction is the ratio of the speed of light in free space, or a vacuum, compared to its speed in the substance.	Index of Refraction for Various Materials Water 1.33 Alcohol 1.36 Turpentine 1.47 Crown Glass 1.53 Flint Glass 1.67 Diamond 2.47	The principle of *refraction* is utilized to control the direction of light by means of prismatic or ribbed glass plates, or in lens systems. It has wide application in certain types of general lighting systems, as well as in signal lighting and street lighting.
Polarization Light in which the waves vibrate in one plane only is said to be *polarized*. The vibrations which make the wave motion in a ray of light are at right angles to the direction in which the light is traveling, and in a beam of ordinary light these vibrations take place in all possible directions in that plane. By passing light through a material with a crystalline structure such that it transmits only waves vibrating in a certain direction, it is possible to produce polarized light, all of whose vibrations are parallel.  				Two polarizing screens are ordinarily used in a system that involves polarization. The first, called the *polarizer*, produces the polarization, and the second, called the *analyzer*, selects or rejects the polarized light, according to the position in which it is placed.	Crystals of Iceland spar, calcite, and tourmaline; Polaroid, (a cellophane-like material available commercially). Reflection from specular or polished surfaces partially polarizes light. Ordinary radiant energy, with waves in a plurality of planes, is not polarized.	The principle of *polarization* is used in certain kinds of laboratory equipment, and in testing for stress and strain in transparent materials; in producing third-dimension effects in motion pictures; in sun glasses and automobile visors to reduce reflected glare from road surfaces and water; in photographic filters. Experimental work on the control of automobile headlight glare by means of polarizing material is under way.

The human eye is tuned to respond only to the energy within the limits of the *visible spectrum*, a narrow band of wavelengths between 3800 Angstroms and 7600 Angstroms.* Energy in this region, evaluated in terms of the eye sensitivity curve is *light*.

Color of light is determined by its wavelength. Light at the short-wave end of the visible spectrum, from 3800 to about 4500 Angstroms, produces the sensation of violet; the longest visible waves, from about 6400 to 7600 Angstroms, appear as red. Between these limits lie the wavelengths which the eye distinguishes as blue (4500-4900 Angstroms), green (4900-5600), yellow (5600-5900), and orange (5900-6400)—the colors of the rainbow.

The spectrum of a light source may be *continuous*, including all the visible wavelengths, or it may be a *line* or a *band* spectrum, containing only one or a few separated groups of wavelengths. A tungsten filament has a continuous spectrum, a mercury arc a line spectrum. An *equal-energy* spectrum—that is, all the visible wavelengths in equal quantities—produces the sensation of white light. Noon sunlight approximates an equal-energy spectrum.

Color temperature is a term sometimes used to describe the color of the light from a source by comparing it with the color of a *blackbody*, a theoretical "complete radiator" which absorbs all radiation that falls on it, and in turn radiates a maximum amount of energy in all parts of the spectrum. A blackbody, like any other incandescent body, changes color as its temperature is raised. The light from a white fluorescent lamp is similar in color to the light from a blackbody at a temperature of approximately 3500 Kelvin,† and the lamp is accordingly said to have a color temperature of 3500 K. The light from a daylight fluorescent lamp is bluer, and the blackbody must be raised to 6500 K to match it. Hence the daylight lamp has a color temperature of 6500 K.

Color temperature is not a measure of the *actual temperature* of an object. It defines *color only*. Some light sources, such as a sodium vapor lamp, or a green or pink fluorescent lamp, will not match the color of a blackbody at any temperature, and therefore no color temperatures can be assigned to them. (See Table 1, p. 27-64.)

TERMINOLOGY AND MEASUREMENTS. Table 2 gives definitions for lighting intensity and other information concerning the quantities used in the measurement of lighting intensity. Table 3 provides data on the modification of light by reflection, transmission, refraction, and polarization.

In general, the following facts regarding light should be kept closely in mind when dealing with illumination problems:

Light travels in straight lines, unless it is modified or re-directed by means of a reflecting, refracting, or diffusing medium.

Light waves pass through one another without alteration of either: for example, a beam of red light will pass directly through a beam of blue light unchanged in direction or color.

Light is invisible in passing through space unless some medium (such as dust) scatters it in the direction of the eye.

10. THE FACTORS OF SEEING

SIZE of the object is the most generally recognized and accepted factor in seeing. The larger an object in terms of visual angle (the angle subtended by the object at the eye) the more readily it can be seen. The familiar eye test chart illustrates this principle (Fig. 2). The person who brings a small object close to his eye in order to see it more clearly is unconsciously making use of the size factor by increasing the visual angle. Under any conditions an object must subtend about a one-minute angle to be seen clearly. Visual acuity, expressed as the reciprocal of the visual angle in minutes, is a measure of the smallest detail that can be seen. Since visual acuity increases markedly with increase in illumination, light is sometimes said to act as a "magnifier," making visible small details that could not be seen with less light.

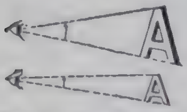

FIG. 2. Visual angle.

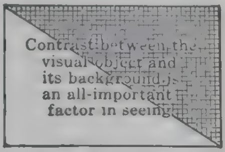
BRIGHTNESS is one of the primary factors in visibility. The brightness of an object depends both on the intensity of the light striking it and the proportion of that light reflected in the direction of the eye. A white surface will have a much higher brightness than a black surface receiving the same illumination. However, by adding enough light to a dark surface it is possible to make it as bright as a white one. The darker an object or a visual task, the greater the illumination necessary for equal brightness and, under like circumstances, for equal visibility.

---

* The Angstrom is a wavelength unit equal to one ten-millionth of a millimeter, or approximately four-billionths of an inch. The *micron*, equal to one-millionth of a meter, is another unit often used to express wavelength. One micron is 1×10^4 Angstroms.

† Kelvin is a temperature scale which has its zero point at −273 C.



Contrast between the visual object and its background is an all-important factor in seeing

FIG. 3. Contrast.

CONTRAST in brightness or color between the visual object and its immediate background is as important for seeing as general brightness level. The difference in the visual effort required to read the two halves of Fig. 3 is a simple demonstration of the effectiveness of contrast. High levels of illumination partly compensate for low brightness contrasts and are of great assistance where poor contrast conditions cannot be avoided.

TIME. Seeing requires time. The dark-adapted eye can see under low levels of illumination, if sufficient time is allowed. "Snapshot" eye pictures require more light energy. The time factor is particularly important where the visual object is in motion.

11. LIGHT SOURCES

The primary purpose of a light source is the production of light, and the efficiency with which a lamp fulfills this purpose is expressed in terms of lumens emitted per watt of power consumed. If a source could be developed that would radiate all the energy it received as monochromatic yellow-green light in the region of maximum sensitivity of the eye, 5550 Angstroms, it would produce approximately 650 lumens for each watt of power consumed. A theoretical source of white light of maximum efficiency, emitting only visible energy without any infrared or ultraviolet, would produce about 200 lumens per watt. Compared with these figures, the best available lamp efficiencies today seem disappointingly low (see Table 4). However, reference to earlier products of lamp manufacture shows the progress that has been made. The efficiency of the 60-watt lamp, for example, has been increased almost 350% during the last 40 years by changing from carbon to tungsten as a filament material, from vacuum to gas-filled construction, and from straight filament wire to coiled and then coiled coil filaments.

Table 4. Efficiencies of Various Light Sources

	Approximate Lumens per Watt
Candle (luminous efficiency equivalent)	0.1
Oil lamp (luminous efficiency equivalent)	0.3
Original incandescent lamp (1879)	1.4
60-watt carbon filament lamp (1905)	4.0
60-watt coiled coil tungsten filament lamp (1947)	13.9
1000-watt general-service lamp (1947)	21.5
No. 1 photoflood lamp (1947)	34.6
400-watt A-H1 mercury vapor lamp (lamp only) (1947)	40.0
40-watt white fluorescent lamp (lamp only) (1947)	58.0

However, the filament lamp has certain characteristics which make it inherently inefficient as a source of light, and, although it is probable that efficiencies will still be raised slightly by further refinements in manufacturing processes, the maximum possible values have already been approached. For any considerable increase in efficiency it is now necessary to turn to another type of light source, the electric discharge lamp. Present mercury vapor lamps have efficiencies of 40 to 65 lumens per watt, and sodium vapor lamps 55 lumens per watt, whereas fluorescent lamps have already reached figures as high as 65 lumens per watt, with every likelihood of further increases.

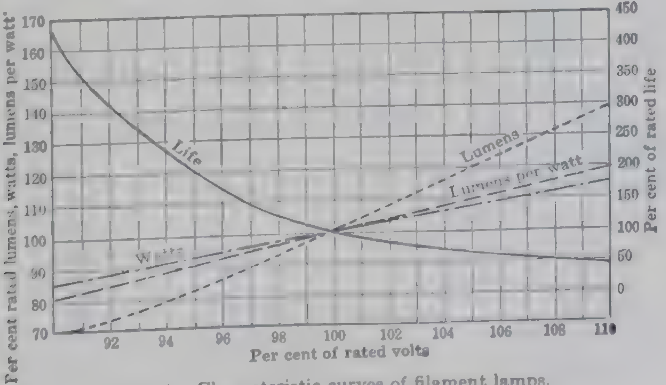


FIG. 4. Characteristic curves of filament lamps.

FILAMENT LAMPS. The typical tungsten filament lamp, in clear or frosted bulb, when burned on a multiple circuit, exhibits the characteristics shown by the curves in Fig. 4. Efficiencies are plotted against rated watts in Fig. 5, and data on lamps of various sizes are given in Table 5. Approximate filament temperatures are indicated in Table 6.

Table 5. Technical Data on Representative 120-volt Standard Filament Lamps

General Lighting Service Lamps

Watts	Bulb	Base	Filament Construction	Rated Average Life, hours	Approx. Initial Lumens	Lumens per Watt

* Standard 120-volt general lighting service lamps.

Shape of a lamp bulb is designated mnemonically by letters (Fig. 6), and the maximum diameter, in eighths of an inch, by figures. For example, a PS-52 bulb is pear-shaped, measuring 6 1/2 in. in diameter. There may be added the bulb glass finish, the base designation, the design volts and watts, and the filament shape, "C" for coiled; "CC" for double or coiled-coil, etc.

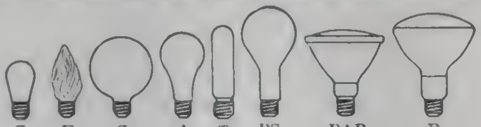

FIG. 6. Lamp bulb shape designations.

FLUORESCENT LAMPS. The fluorescent lamp is essentially an electric discharge source. It consists of a tubular bulb having electrodes sealed into each end and containing mercury vapor at low pressure with a small amount of argon (for starting), Fig. 7. The inner walls of the bulb are coated

(Continued on p. 27-76)

[1] Lamp watts, nominal overall length (one lamp plus two standard lampholders), and bulb designation (T for tubular, number indicates tube diameter in eighths of an inch).

[2] Minimum open-circuit volts at rated line voltage of ballast.

[3] Center value.

[4] Lumens when measured at 80 F ambient, and under specified test conditions. The light output of a new lamp will appreciably exceed the above rated initial values, which apply when the lamps have burned 100 hr.

[5] The majority of lamp types are available also in warm white and soft white.

[6] Regularly available also in blue, green, gold, pink, and red.

[7] A low-temperature 40-watt T-12 lamp, marked with the letters "LT," gives reliable starting down to 0 F.

[8] Base pins shorted inside base.

[9] Slimline lamps may be operated at any intermediate value within their design current range The light output increases with the current loading.

[10] Operates on standard 100 w ballast.

---

[1] The A-H6 is water cooled and requires an outer water jacket, generally of quartz or 774 heat-resisting glass. A similar lamp for air jet cooling is the B-H6 rated at 900 watts.

[2] For total wattage add transformer watts which range from 8 to 25% of lamp watts, depending chiefly on the type of lamp and transformer used.

[3] The A-H6, A-H9, and B-H9 are single-bulb lamps. The outer bulb is the arc tube.

[4] Life of the S-4 and RS sun lamps is rated at 1000 applications in normal sun lamp use in the home, or 1000 hours at 5 hr per start.

[5] Rated average life at 5 hr per start for D-H1 in any position is 1000 hr. At 10 hr per start the rated average life is 3000 hr in the vertical position only.

[6] The A-H1 and F-H1 are designed for base up burning, the B-H1 for base down burning. These types must be operated within 10° of vertical.

[7] For normal indoor use. Higher open-circuit voltages are desirable for dependable starting at lower temperatures.

[8] For 50-60 cycle a-c operation only. Operates directly from regular lighting circuit, no transformer required.

with fluorescent powders which give off light when activated by ultraviolet energy. When the proper voltage is impressed on the electrodes, a flow of electrons is driven from one electrode and attracted or pulled to the other. As these electrons speed through the tube they collide with the mercury atoms, causing a state of excitation which produces short-wave ultraviolet radiation (2537 Angstroms). The fluorescent powders, commonly known as phosphors, absorb this invisible energy and radiate visible light. Table 7 gives data on fluorescent lamps and Table 8 on mercury vapor lamps.

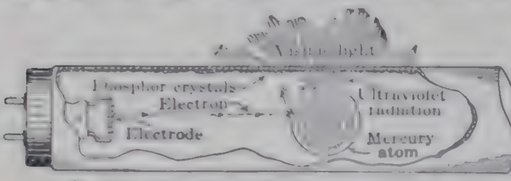

Fig. 7. Principle of the fluorescent lamp.

12. ILLUMINATION LEVELS

The high levels of illumination produced by natural daylight are desirable for many seeing tasks. Before the development of modern light sources many severe visual tasks had to be performed only in daylight hours because of the weakness and expense of illumination provided by the artificial illuminants then in use. The illumination intensities which were considered to be standard in past years were largely determined by the light sources then available. Present-day practice recognizes that the foot-candle levels now recommended do not represent the ultimate in see-ability. They do, however, represent practical values which may readily be obtained by means of existing equipment.

The relationship between foot-candle levels and ability to see is geometric rather than arithmetic, and the chart in Fig. 8 lists approximately equal steps in foot-candle effectiveness.

The quantitative requirement for good illumination of a specific seeing task is primarily a function of the difficulty of the task in terms of fineness of detail, brightness or color contrast, and the speed demanded. Other factors such as the length of time for which the task is to be performed, the surrounding conditions, and the physiological state of the eyes which have to do the work are also involved.

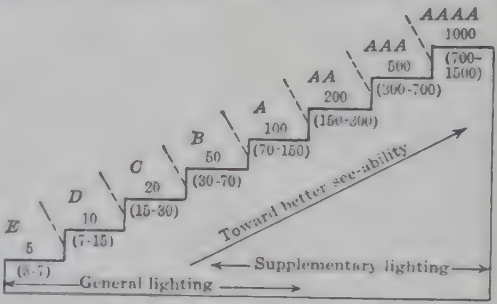

Fig. 8. Levels of illumination.

GENERAL LIGHTING. The following classification of foot-candles assumes substantially white light illumination on the work or target, not in the eyes. Usually the values are those maintained in service, or the going average; and if a work plane is not specified, it is assumed to be the horizontal surface 30 in. above the floor.

Level A—100 Foot-candles. For very exacting and prolonged seeing tasks, such as fine bench and machine work, extra fine hand painting and finishing, and for the discrimination of fine detail of low contrast. For showcases, wall cases and open counter displays in stores and reading medium to fine print, or sewing. (Under various circumstances the foot-candles may range from 30 below to 40% above the value given.)

Level B—50 Foot-candles. For severe and extensive seeing tasks, such as medium and fine machine work, medium fine assembly and inspection; fine sanding and finishing of woodwork, drafting, and proofreading. For general merchandising areas in stores. (Range—minus 30 to plus 40%.)

Level C—20 Foot-candles. For moderately critical and lengthy seeing tasks, such as rough bench and machine work, medium assembly and inspection, hand painting and finishing, for weaving light woolens and reading large type. For circulation areas in stores. (Range—minus 30 to plus 40%.)

Level D—10 Foot-candles. For visually controlled work in which seeing is important, but more or less interrupted or casual, and does not involve discrimination of fine details or low contrasts. For rough manufacturing processes, such as molding clay products and cements, glass-blowing machines, billet, blooming and bar mills in steel manufacturing. For stockrooms and active storage areas for a variety of small articles such as for merchandise stocks.

Level E—5 Foot-candles. For exteriors where crude manual tasks are intermittently carried on, such as required for grinding clay products and cements, stone crushing, hand furnaces and boiling tanks in chemical plants, stockrooms and active storage areas for medium-size materials; for the safe assembly or movement of people in auditoriums, through corridors and stairways. For active work areas out-of-doors—loading docks.

SUPPLEMENTARY LIGHTING. Level AA—200 Foot-candles. For extra fine inspection, such as required in making jewelry and precision instruments. For featured items and merchandise displays in show windows in secondary business areas of large cities. (Range—minus 30 to plus 40%.)

Level AAA—500 Foot-candles. For feature merchandise displays in show windows in main business areas of large cities. For color identification in industry. (Range—minus 30 to plus 40%.)

Level AAAA—1000 Foot-candles. Outdoor levels of illumination. For photography, hospital operating rooms, and the daytime illumination of show windows. (Range—minus 30 to plus 40%.)

STREET LIGHTING. Average foot-candles or lumens per square foot on roadway, based on medium reflectance of surface on the order of 10%, and for urban streets are:

Pedestrian Traffic Likely to Cross	Vehicular Traffic Classification			
	Very Light (Under 150)	Light (150–500)	Medium (500–1200)	Heavy (1200 up)
Heavy	...	0.8	1.0	1.2
Medium	...	0.6	0.8	1.0
Light	0.2	0.4	0.6	0.8

13. INTERIOR LIGHTING DESIGN

BASIC FORMULAS for interior lighting design are:

$$\text{Total lumens} = \frac{\text{Foot-candles} \times \text{area}}{\text{Coefficient of utilization} \times \text{maintenance factor}}$$

$$\text{Number of lamps} = \frac{\text{Foot-candles} \times \text{area}}{\left\{\begin{array}{l}\text{Lumens per lamp} \times \text{coefficient of utili-}\\ \quad\text{zation} \times \text{maintenance factor}\end{array}\right\}}$$

$$\text{Luminaires} = \frac{\text{Foot-candles} \times \text{area}}{\left\{\begin{array}{l}\text{Lamps per luminaire} \times \text{lumens per lamp} \times \text{co-}\\ \quad\text{efficient of utilization} \times \text{maintenance factor}\end{array}\right\}}$$

$$\text{Foot-candles} = \frac{\left\{\begin{array}{l}\text{Lamp lumens} \times \text{coefficient of utilization} \times\\ \quad\text{maintenance factor}\end{array}\right\}}{\text{Area}}$$

$$\text{Area per luminaire} = \frac{\left\{\begin{array}{l}\text{Lamps per luminaire} \times \text{lumens per}\\ \quad\text{lamp} \times \text{coefficient of utilization} \times\\ \quad\text{maintenance factor}\end{array}\right\}}{\text{Foot-candles}}$$

Total (generated) lumens are determined by the published initial lumen figures given for each type or size of lamp, multiplied by the number of lamps involved.

Foot-candles are either measured by a light meter, or pre-chosen from published tables of desirable intensities.

Areas are normally the square footages of the floors or of a large area target.

Maintenance factor is the combined allowance for dirt on the fixture or immediate surroundings and the normal reduction in lumen output of the lamps themselves. This factor, for medium maintenance and average (70% life point) condition of lamp, is roughly 55%. Poor cleaning might reduce this to 40%; good maintenance raise it to 70%.

Coefficient of utilization expresses the percentage of generated (lamp) lumens that reach the work area or target. It takes into account the lumens lost in the fixtures or reflector, plus those absorbed by floors, ceilings, and walls that are not the work areas. The larger the room, the less light is lost on walls. Fifteen to 35% of the generated lumens is lost through fixture absorption, so that for an average office installation of fluorescent luminaires, this coefficient may be taken as roughly 50%; for large factories, with open-bottom industrial reflectors, about 70%.

Example. **To illuminate a large, clean general factory space, 60 by 200 ft, for medium rough machine operations,** the advisable foot-candles would be chosen to average, say, 30. If using fluorescent (100 watt) lamps in open reflectors, the coefficient of utilization would be about 70%. With good maintenance, the maintenance factor would be roughly 65%. Therefore

$$\text{Total lumens} = \frac{30 \times 12{,}000}{0.70 \times 0.65} = 792{,}000$$

Each 100-watt (white) fluorescent lamp is rated at 4600 lumens, so 172 lamps are needed.

INTERIOR WIRING FOR LIGHTING. After determining the foot-candles needed for a general-purpose interior, the required power in watts per square foot of floor area may be roughly estimated from the chart in Fig. 9. This assumes good maintenance, a light color of interior surfaces, and medium-sized rooms.

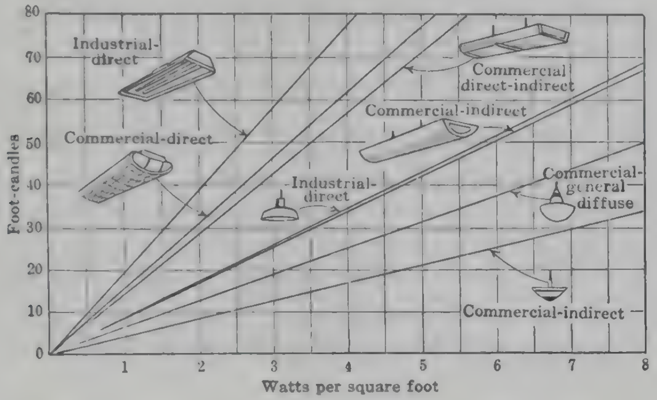

FIG. 9. Power required for commercial and industrial lighting.

Manufacturing areas should have at least one convenience outlet for every 20 linear ft of wall space; private commercial offices, one outlet for each 10 ft of baseboard.

The wire sizes for various ampere loadings and the voltage losses for different lengths of run (of circuit, not of single wire) are given in Tables 9 and 10.

SAFETY ENGINEERING

By Sidney J. Williams and A. M. Baltzer

14. BASES OF ACCIDENT PREVENTION

The guarding of dangerous machinery and dangerous places is required by the laws of most states. High accident rates are penalized, also, by an increase in the rate charged for workmen's compensation insurance.

Most industrial concerns endeavor to eliminate or guard all danger points and to correct all unsafe practices, even where not demanded by state or insurance requirements because they have found that: (1) Accidents cause, or indicate, an irregularity in production that results in lost time and inefficiency. (2) Accidents cause the temporary or permanent loss of experienced and valuable workmen. (3) Careful attention to safety, by both mechanical and educational means, raises the morale of the working force. Such companies often require that equipment which they purchase be guarded in accordance with certain specifications.

A generation of accident-prevention experience in American industry has proved that safety engineering is indispensable to efficient production and that any organization, large or small, can protect itself against unnecessary loss. In the 19-year period of 1930–1948 the industrial injury frequency rate of thousands of companies reporting to the National Safety Council dropped an average of over 38% whereas the severity rate went down over 43%. It has been established that practically all accidents are preventable and that most of them involve both personal and mechanical causes.

PRINCIPLES which guide industry's effort are:

1. Management must be sincerely interested and must give continuing and active support to the program.
2. Supervisors must accept clearly defined responsibilities for the removal of hazards within their departments.
3. The accident-prevention program must be directed by a capable person on a full or part-time basis.
4. The nature of the problem must be known through an analysis of accident records and an inventory of physical hazards.

5. Unsafe conditions must be made safe, machines must be guarded, protective equipment must be provided, housekeeping must be improved, and physical hazards must be removed.
6. Supervisors and employees must be trained to do their jobs safely.
7. Simple but informative accident records must be kept so that trends may be known and accident-producing causes eliminated.
8. Regular inspections must be made to detect and correct hazards *before* they cause accidents.
9. First-aid and sanitation facilities must be established and supervised by trained personnel.
10. The interest of employees must be maintained on a high level so that they cooperate in the program.

ADMINISTRATION OF THE SAFETY PROGRAM is entrusted to a safety director who in larger companies has had specialized training and devotes full time to this work. In smaller and medium-sized companies, safety is combined with personnel, industrial relations, insurance, or other functions. In all cases the safety director analyzes accident causes, and effects their removal through recommendations to top management. He exerts no "line" control over production. In some companies, however, the safety engineer is given authority, if need be, to stop operations immediately hazardous.

In starting or rehabilitating a safety program, help should be sought early from the organizations listed in Article 23.

15. PLANT DESIGN AND EQUIPMENT

Safety features built into the plant reduce the need for costly alterations later.

RAILROAD SIDING clearances are subject to control by state public utility commissions but in general they require 4-ft clearance between the nearest rail and the sides of buildings or other obstructions. Overhead clearance must be at least 22 ft from rail to the under side of structures or building entrances and at least 35 ft from high-tension power lines.

AISLES should be not less than 2 ft wider than the widest vehicle loaded. For two-way traffic, the aisle should be not less than 3 ft wider than twice the width of the widest vehicle loaded. Aisle areas should be clearly marked with stripes of a contrasting color painted on the floor. The speed of trucks is generally limited to 6 or 8 miles per hour.

EXITS must be adequate for any emergency. At least two, remote from each other, should be provided for each room or working area in conformance with the Building Exits Code of the National Fire Protection Association.

STAIRS should preferably be at an angle of 30 to 35 degrees from the horizontal with treads, exclusive of the nosing, at least 9 1/2 in. wide and risers not over 8 in. high. For heavy traffic the stair treads, particularly the nosing, should be surfaced with a nonslip material to prevent falls.

HAND RAILS 30 to 34 in. in height above the stair nosing are specified by the American Standard Code for Railings and Toe Boards. Stairs less than 44 in. wide, with both sides enclosed, should have at least one hand rail on the right side descending. Stairways between 44 and 88 in. require hand rails on each side and over 88 in. an additional hand rail in the center.

FLOOR OPENINGS require enclosure with a 42-in. high standard railing, a 4- to 6-in. toeboard at the floor level, and an intermediate rail approximately 18 in. above the floor.

FLOORS must be strong enough to support machine and human loads, loaded power trucks, and the heaviest material that might be stored on them. Floors should be as level as possible and smooth without being excessively slippery.

ACCESS should be provided, by runways and stairs or permanent ladders, to all points which must be visited for maintenance, cleaning, oiling, or other purposes.

PIPES and other equipment should not encroach on safe headroom (at least 6 ft 6 in.) over stairs and passageways.

ELECTRICAL HAZARDS. High voltage equipment should be available only to specially trained employees authorized to work with it. Transformers, switchboards, and other exposed parts can be protected by grounded enclosures or standard railings and by grounding noncurrent-carrying metal parts as recommended by the National Electrical Code of the National Bureau of Standards. Warning signs and devices for locking out equipment under repair provide further protection.

Plant wiring should also conform to the National Electrical Code and to local codes. Makeshift wiring should be eliminated because of the shock and fire hazard. Extension cords and other equipment should be of a type listed by Underwriters Laboratories.

STEAM BOILERS. Special safety measures include provision for tagging and locking valves while boilers are under repair, reinforced gage glass guards, enclosure of stoker drives, and safe, convenient access to all overhead work areas. Refer also to ASME Power Boiler Code.

UNFIRED PRESSURE VESSELS. Compressed air tanks, steam-jacketed kettles, digesters, vulcanizers, and similar equipment should be designed and constructed in accordance with the ASME Code for Unfired Pressure Vessels. The hazard of corrosion, external damage, or collapse due to vacuum is aggravated if such equipment is operated by untrained persons. Regular inspection and maintenance of safety valves, rupture disks, fusible plugs, and relief valves are of great importance.

GOOD LIGHTING is conducive to operating efficiency and the prevention of accidents. Good general lighting requires at least 10 foot-candles at the work level and avoidance of glare and strong shadows.

GENERAL VENTILATION prevents the accumulation of dust, fumes, and vapors without excessive draft. However, general ventilation is not an adequate substitute for local exhaust, whereby harmful materials are removed close to their source.

OVERHEAD EXHAUST HOODS are suitable only where the material is heated or is lighter than air and then should be designed so that the harmful materials are not drawn past the breathing level. Down-draft exhausts are suitable for the collection of dust, such as in a foundry shakeout, and for the collection of solvent vapors which are generally heavier than air.

LADDER shoes of abrasive material, rubber, cork, or sharp spikes will prevent slipping, but lashing or otherwise holding the ladder is recommended. For regular or continuous work, safety platform ladders, equipped with guard rail, are recommended.

SCAFFOLDS 10 ft or more above the ground or floor should be equipped with guard rails and standard toeboard. The principal causes of scaffold accidents are poor or defective materials, poor construction, overloading, and the falling of men or materials due to inadequate protection.

PIPING IDENTIFICATION systems help prevent confusion which may cause injury. The following classifications are recommended by the National Safety Council and the American Standards Association:

Fire protection materials and equipment (F)—red.
Dangerous materials (D)—yellow (or orange).
Safe materials (S)—green.
Protective material (P)—bright blue.
Valuable materials (V)—deep purple.

More specific identification can be accomplished by stenciling a painted legend on each pipe or by adding one or more color stripes in conformance with the standard code.

WARNING SIGNS and tags are particularly useful in locking out valves and boilers and chemical or petroleum pipelines, for warning employees against the starting of electrical equipment while repairs are being made, for preventing smoking in hazardous areas, for identifying high-voltage electrical equipment, and for instructing employees on the use of personal protective equipment or machine guards.

FIRST-AID FACILITIES. Large companies generally provide professional medical personnel with at least one or more registered nurses in attendance on all shifts. Smaller plants train competent first-aid attendants for treating very minor injuries and for rendering emergency care for serious injuries. The advice of insurance companies and private physicians should be sought in setting up first-aid facilities adequate for the exposure.

Minimum first-aid room equipment includes two chairs, a small table, running water, wash basin, soap, paper towels, waste basket, and a dustproof, well-equipped cabinet of needed materials. It is particularly desirable to provide cots made private with screens.

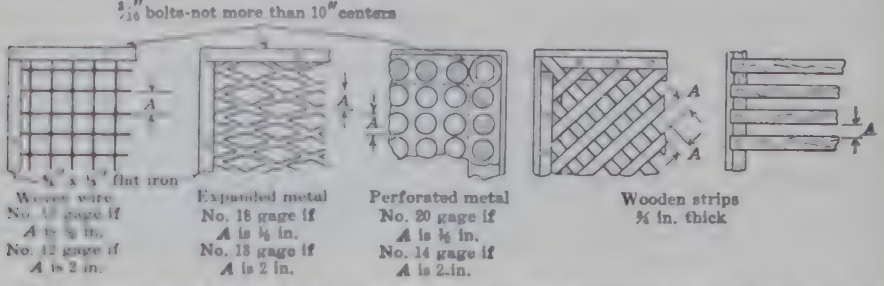
16. MACHINE GUARDING

Machinery must be reasonably well guarded before management can expect supervisors and employees to cooperate wholeheartedly in the safety program.

ESSENTIALS OF GUARDING. Built-in guards are always preferable to built-on guards. Temporary, makeshift, and flimsy guards not only give a false sense of security but also imply that management is not sincere in its efforts to protect the employee.

Excellent commercial guards are available from machine manufacturers and from distributors of safety equipment. Guards should be constructed in conformance with the codes of the American Standards Association and pamphlets of the National Safety Council. State codes generally represent only minimum requirements, and positive protection often requires more thorough treatment. A good guard: (1) Provides positive protection and prevents all access to the danger zone during operations. (2) Does not interfere with the operation of the machines; permits convenient and safe lubrication, adjustment, and repairs. (3) Is strong and durable, fire and corrosion resistant. (4) Does not have splinters or sharp edges and projections which might cause injury. (5) Is designed to prevent tampering and yet permit authorized removal and adjustment. (6) Does not interfere with the operator or cause eye strain or other discomfort.

GUARD MATERIALS. Sheet metal, heavy wire mesh, expanded metal, pipe, and structural steel are most commonly used (Fig. 1). Cast iron should not be used where impact resistance is required; wood guards are permissible in exposures which might corrode metals; shatterproof glass and transparent plastic are used where visibility rather than strength is required.



Solid sheet metal guards should be No. 22 gage or heavier. Supports should be 1 in. or 1½ in. angle iron or ¾ in. to 1½ in. ID pipe.

If the distance from moving part to guard is less than 4 in., opening *A* should not exceed ½ in. For distances more than 4 in. and less than 15 in., opening *A* should not exceed 2 in. except wooden slot guards where *A* should not exceed 1 in.

FIG. 1. Guard materials. (Reproduced by permission from *Accident Prevention Manual for Industrial Operations*, National Safety Council)

Where resistance to rust or possible damage to tools is an important factor, guards of aluminum or other alloy are often used. Guards exposed to trucking operations and the movement of material are often protected by extra bumpers.

PRIME MOVERS AND TRANSMISSION MACHINERY GUARDS. Flywheels and other heavy machine parts which cannot be completely enclosed or otherwise guarded should be protected by standard 42-in. high railings placed not less than 6 or more than 20 in. from the flywheel or other moving part, (Fig. 2). Standard 6-in. toeboards are necessary where there is a floor opening or pit. Governor balls, couplings, belts, and pulleys 6 ft. or less from the floor or working platform should be enclosed with a substantial guard.

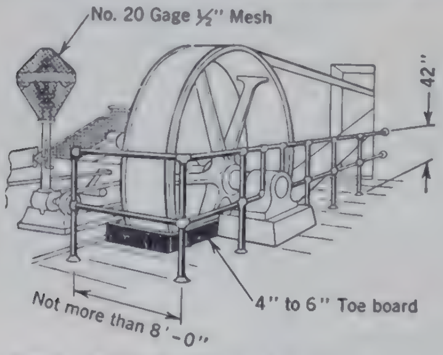


FIG. 2. Standard railing and toeboard, guarding flywheel and belt too large to be enclosed. Note governor enclosure. (National Safety Council, *op. cit.*)

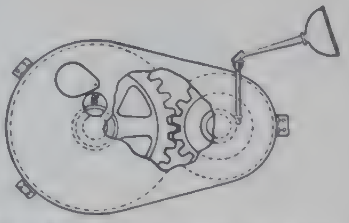

FIG. 3. Solid sheet-metal gear guard, illustrating arrangements for safe oiling. The swinging opening at the left provides access for a grease gun; the pipe through the guard at the right permits use of an oil can with safety. (National Safety Council, *op. cit.*)

Where machinery must run during oiling and when automatic lubrication is not feasible, remote-control devices provide the best protection. Oil holes in guards can be designed so as to permit access for the end of the oil can spout but not the hands (Fig. 3). Central oiling systems are becoming more widely used as they also speed the oiling.

BELTS AND BELT GUARDS. Standard codes call for the guarding of V-belts, round belts more than 1/2 in. in diameter, and flat belts more than 2 in. wide, running at 250 ft per min or more. (See Figs. 4 and 5.) Larger belts are likely to cause serious injury if they break and whip about, and belts of all sizes with metal lacings may cause scratches and cuts, and even catch unprotected hair.

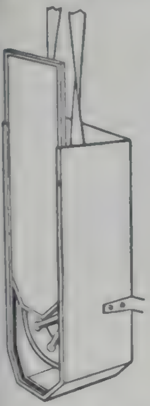

FIG. 4. Sheet-metal guard for vertical belt, with one side removable for access to moving parts. Note movable side falls automatically into place. (National Safety Council, *op. cit.*)

If belt dressing must be applied while the belt is in motion an opening may be built in the guard so that the dressing can be applied near the point where the belt *leaves* the pulley.

Leather and rubber belts tend to create static sparks which may ignite flammable liquids, dusts, or gases. Conductive dressings can be applied, but conductive rubber belts are better. Static brushes or collectors can also be used to drain away excessive static.

Horizontal belts should be totally enclosed if both the upper and lower runs are less than 7 ft from the floor or working area; the lower run should be enclosed if it is less than 7 ft above the working floor.

All belts traveling more than 1800 ft per min or located directly over aisles or work areas should have the lower run and pulley enclosed on the sides and bottom.

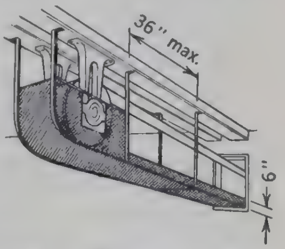

FIG. 5. Typical horizontal belt and pulley guard with removable sides. (National Safety Council, *op. cit.*)

Vertical and inclined belts should be enclosed so that no portion of the exposed belt is less than 6 ft 6 in. from the floor (Fig. 6). Pulleys lower than 7 ft above the floor should be enclosed up to that point.

To facilitate cleaning the floor, guards should be attached to the machine rather than supported from the floor.

Belt shifters with positive locks prevent accidental starting. Belt shipper poles for placing belts on moving pulleys obviate the need to shift belts by hand, and the latter practice should be prohibited. Belts should always be unshipped by throwing them off the *driving* pulley. "Do not use" tags should be used on belt shifters to prevent unauthorized starting of the machine while someone is working on it.

GEARS, SPROCKETS AND CHAINS. Power-driven gears and sprockets should be guarded by complete standard enclosures with no openings larger than 1/2 in. if the guard is within 4 in. of any moving part, or not larger than 2 in. if the guard is between 4 and 15 in. from the moving part. Guards which enclose only the teeth of gears or which shield only the in-running nip point are accepted by some state codes. They are not so safe as complete enclosures, however, because they do not provide positive protection against persons falling or slipping into them.

Chains require the same guarding as belts.

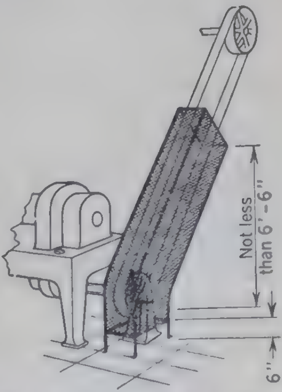

FIG. 6. Inclined belt totally enclosed to a height of 6 ft, 6 in. above floor. Note 6 in. clearance to permit cleaning floor. (National Safety Council, *op. cit.*)

SHAFTING, COUPLINGS, AND KEYS. Many serious accidents have occurred when hair, wiping rags, or loose clothing has caught on smooth shafting. Horizontal or vertical shafting within 7 ft of the floor should be guarded by fixed barriers or three-sided trough guards, the open end of which extends at least 2 in. beyond the nearest side of the shaft. Pulleys, shafting, and other moving parts located less than 15 ft above aisles or passages used by power-driven vehicles should be similarly enclosed.

Shaft ends which project beyond pulleys or bearings should be enclosed, and open keyways should be filled or enclosed. Projecting keys should always be cut off flush with end of shaft.

Bolts, nuts, and set screws on couplings should be of the countersunk flush type, or the coupling should be completely enclosed with a stationary guard.

POINT OF OPERATION GUARDS should be as nearly foolproof as possible. They may be of the following types.

Automatic or semi-automatic feed with enclosure so that no part of the body can reach the moving part. Example punch presses, wood planers.

Two-hand trip, either electrical or mechanical, which require simultaneous pressure of two hands on separated buttons while the dangerous part is in motion. Example—punch presses, paper cutters, dough mixers.

Complete fixed enclosure which admits only the stock being fed. Example—metal square shears, punch presses.

Adjustable barrier which admits only the stock being fed (Fig. 7). Example—candy-cutting rolls.

Warning enclosures which admit stock thicker than the hand and, therefore, also the hands, but tend to deflect the hand or remind the operator that he is entering the danger zone. Example—circular saw and jointer guards.

Barrier with electric contact or mechanical stop actuating a mechanical or electric brake (Fig. 8). Approach of any part of the body to the danger zone stops the machine. Example—punch presses, rubber mills, paper calenders.

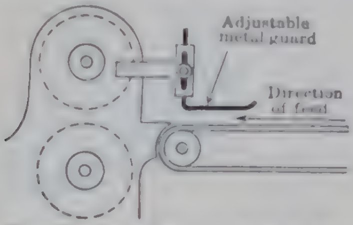

Fig. 7. An adjustable barrier, projecting horizontally, permits a feed opening large enough to admit stock but not the arm of the operator. (National Safety Council, *op. cit.*)

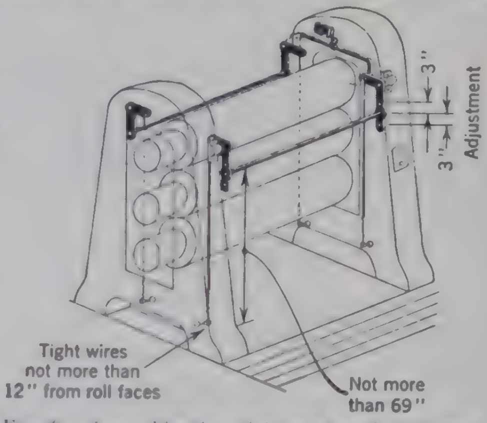

Fig. 8. A combination tight wire and rigid bar device, when touched, trips a contact and stops rolls before the operator is caught by them. (National Safety Council, *op. cit.*)

Enclosure with electrical or mechanical interlock. Opening of guard stops the machine and starting the machine closes the guard. Example—laundry extractors, foundry tumblers, punch presses.

Hand-removal guards of the sweep or hand-pullaway type connected to the machine to remove the hand from the danger zone. Example—hand-fed platen presses, punch presses, leather-embossing presses.

Limiting plunger travel to $\frac{3}{8}$ in. or less so that fingers cannot enter the danger point. Example—kick presses, punch presses.

Electric eye; interruption of the beam actuates a brake which stops the machine. Example—punch presses, embossing presses.

Special tools or handles on dies; long-handled tongs, vacuum lifters, or holders eliminate the need for the operator to place his hand in the danger zone. Example—leather and textile die cutters.

Special jigs or feeding devices which keep the operator's hand at a safe distance from the danger point through use of a fixed or movable enclosure built to fit the stock. Example—circular saws, jointers, punch presses.

Enclosures which by their complex shape or size of opening prevent the operator from reaching the moving part.

WOOD-WORKING MACHINERY. Circular table saws, jointers, band saws, swing saws, and sliding yoke circular saws are commonly used in most industries and cause a great many disabling injuries.

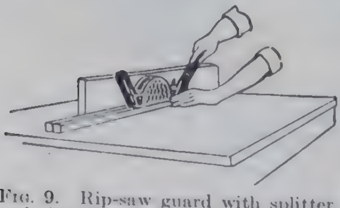

Fig. 9. Rip-saw guard with splitter and built-in anti-kickback device. For extra safety, the operator uses a push stick. (National Safety Council, *op. cit.*)

Circular rip saws require a lightweight hood enclosure of soft metal, a splitter to prevent the work from binding on the saw, and an anti-kickback device (Fig. 9). All parts of circular saws should be completely enclosed above and below the work table. Sometimes an exhaust system for the removal of chips serves to enclose the lower part of the saw. Swing saws or sliding yoke saws require a device which will limit the length of the saw travel and prevent bouncing. Saw guards should provide a view of the cut. The operator should stand to one side of the line of the cut, the floor surface should be free of obstructions and not slippery, and a push stick should be used for feeding short pieces of stock.

Jointers and planers. All jointers should have cylindrical safety heads with only enough clearance between the head and the table for the knife to clear. A fixed or adjustable guard should cover the unused end of the head, and an adjustable guard should completely cover the operating side of the head (Fig. 10). These guards may be of the swinging type or of the type that rises and rides on top of the work, as well as swinging in a horizontal plane. The latter type of guard gives better protection for surface joining.

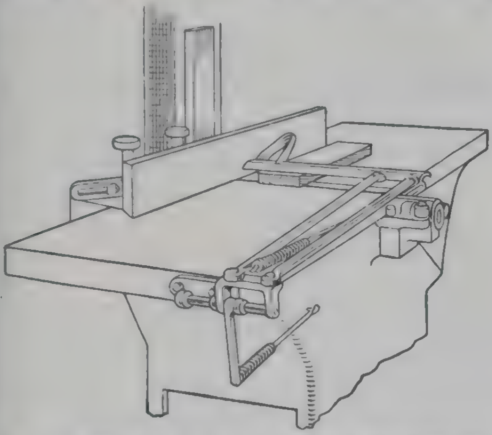

FIG. 10. This jointer guard swings and also rises over the work to permit safer surfacing. The knife on the other side of the guide is fully protected by an automatic guard. (National Safety Council, *op. cit.*)

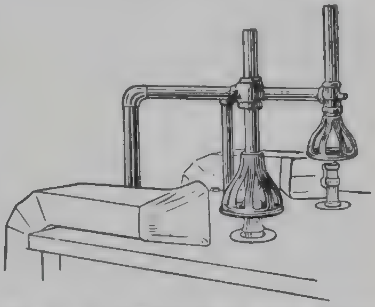

FIG. 11. Adjustable shaper head guards, with exhaust pipes to remove chips. (National Safety Council, *op. cit.*)

A small push block provides an additional margin of safety when feeding short stock. The hands should be kept well back on the work—never over the end of the stock as it is fed into the knife.

Band saw wheels should be completely enclosed. The only portion of the blade exposed should be that necessary for the thickness of stock being cut. An adjustable guard set close to the work will minimize the length of saw blade exposed.

Shapers require an adjustable ring or bell-shaped guard (Fig. 11). The extreme hazard of shaper knives being thrown can be reduced by the use of solid cutters, perfectly balanced knives, and safety collars which tend to retain the knife.

METAL-WORKING MACHINERY. Power Presses. Most of the methods of guarding points of operation listed previously can be applied to power presses. Length of run and type of job often determine the type of guard that can be used—an expensive, automatic feeding device or a simple barrier enclosure. With all points of operation guarded, power press nonrepeat devices provide an additional factor of safety.

Many plants have adopted the policy of building a guard for or into each die. This assures maximum production efficiency and gives the operator no excuse for neglecting to use the guard.

Foot treadles can be protected against accidental tripping through the use of sheet metal hoods (Fig. 12).

A regular system of inspection and maintenance for power-press guards is imperative, to insure safe condition and proper adjustment. The action of the guard should be tested before each run is started and, in the case of the two-hand pull back guard, for the individual operator's reach.

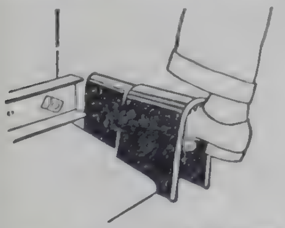

FIG. 12. Substantial hood guard over foot treadle prevents accidental tripping of power presses and similarly controlled machines. (National Safety Council, *op. cit.*)

Grinders and abrasive wheels require substantial metal hood guards and safety flanges. (See Fig. 13, p. 27-101.) The tool rest should be set within $^1/_8$ in. of the wheel to prevent fingers or stock being caught between the rest and the wheel. (See Fig. 13.)

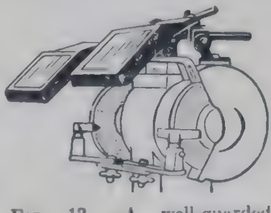

FIG. 13. A well-guarded grinder with safety glass shields and tool rests adjusted to within $^1/_8$ in. of the abrasive wheels. (National Safety Council, *op. cit.*)

Safety-glass shields with built-in light to illuminate the point of operation reduce the danger of flying objects, but safety goggles or plastic eye shields should also be worn where there is danger of heavy impact. Gloves should not be worn on abrasive wheels or other moving machinery of similar type.

Abrasive wheels should be provided with exhaust hoods, particularly if the work involves grinding or polishing of material which gives off toxic dusts. See the American Standards Association Safety Code for the Use, Care, and Protection of Abrasive Wheels.

Lathes. All gears should be completely enclosed and, where possible, speed changes should be handled mechanically. Safety dogs without projecting parts should be used, and a guard over the chuck is advisable. Splash shields and drip pans will prevent cutting oil from reaching the floor and causing falls.

Square shears are comparatively easy to guard through the use of simple barriers of iron bars, expanded or slotted metal. The take-off side of the shears should also be guarded by position or by a barrier.

17. MATERIALS HANDLING

Approximately one-fourth of all compensated injuries result from unsafe methods of handling and moving materials. Of this number, about half are due to improper lifting. The substitution of mechanical handling does not necessarily bring about an improvement in experience even though the exposure has apparently been reduced. Since mechanical methods are more subject to engineering and management control, however, it is considered good practice to revise procedures to take advantage of mechanical aids.

MANUAL HANDLING. Lifting injuries such as back strains may be caused by improperly lifting even a light object. The U. S. Department of Labor sets up the following limits for continuous or repetitive lifting operations: male workers—50 lb in compact form; female workers—25 lb in compact form.

Employees should be trained and reminded to lift according to the following principles: (1) Bend the knees and lift with the legs, not the back. (2) Keep the load close to the body and avoid lifting in an awkward or twisted position. (3) Get good footing and a solid grip. (4) Get help or use mechanical equipment for heavy or awkward loads. (5) Don't jerk the load or attempt to throw it.

MECHANICAL HANDLING. Two-wheel and four-wheel hand trucks are responsible for a great many serious injuries. Truck handles should not project into aisles, and truck handles should have metal guards to protect the hands and fingers.

In general, four-wheel trucks should be pushed; two-wheel trucks should be pulled up an incline and pushed down an incline. On level and smooth floors a decision to push or pull a two-wheel hand truck depends on the amount of traffic, visibility, size of the load, and convenience in unloading or loading the truck.

Electric or gasoline power trucks require the establishment of traffic rules which should be rigidly enforced. Riding of unauthorized persons on trucks must be strictly prohibited. The operator of high-lift trucks should be protected from falling objects by a strong overhead guard. Material to be piled safely must be cross tied, kept within safe floor load limits, and should not project into aisles or obstruct overhead sprinkler heads.

18. HAND TOOLS

Facilities for inspecting and maintaining hand tools should be provided by management. Employees must be constantly reminded (1) to use the right tool for the job, (2) to keep the tool in good condition and turn in defective tools, (3) to use tools correctly, and (4) to store and carry tools in a container, kit, or other safe place.

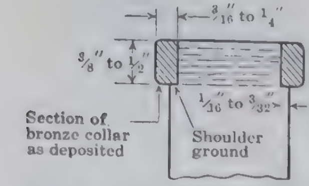

FIG. 14. Bronze collar on hammer-struck tools reduces dangerous mushrooming of tool heads. A bronze-ended tool also outlasts three ordinary tools without cracking. (National Safety Council, *op. cit.*)

Hammerstruck tools, such as chisels and punches, are known for their tendency to develop mushroom heads which frequently chip off, causing the loss of an eye or other serious injury. At the first sign of mushrooming, tool heads should be either dressed or safe-ended by the addition of a bronze collar, (Fig. 14). A regular schedule for dressing or bronze tipping is advisable.

PORTABLE ELECTRIC TOOLS. Potential accident hazards are electric shock, burns, cuts, and injuries from flying particles or dropping tools. The preventives are selection of the right tool, regular inspection and maintenance, and training in proper use.

Grounding of noncurrent-carrying metal parts is particularly important. The best ground consists of a third wire within the power cord, one end connected to the metal body of the tool and the other to a three-prong socket which is automatically grounded when the circuit is completed (Fig. 15).

Extension cords should be checked for breaks in the insulation, for loose plugs, and for other hazards which might cause shock. For work in extremely wet areas or inside steel tanks it is advisable to use 6-volt tools and a portable transformer.

Moving parts of portable power saws, wire brushes, and abrasive wheels should be enclosed in standard guards. Eye protection is important where there is danger of sparks and flying objects.

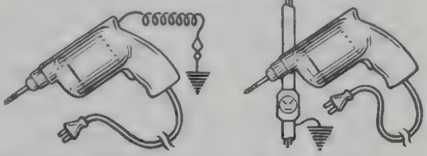

Fig. 15. Methods of grounding portable power tools. At left, a separate ground wire to metal casing; at right, the ground wire is built into the extension cord and a three-prong plug automatically grounds the tool. (National Safety Council, *op. cit.*)

19. PERSONAL PROTECTIVE EQUIPMENT

Personal protective equipment should not be regarded as a "cure-all" or substitute for built-in safety. However, it does have its place as secondary protection, particularly where no other protection is possible or where the operation is of such short duration that other methods are not practicable.

EYE PROTECTION. Hardened glass goggles, plastic eye shields, and plastic face shields provide protection against sparks, dust, flying objects, glare, and splashes of corrosive chemicals or molten metal. See the American Standards Association Code for Protection of Heads, Eyes, and Respiratory Organs, Z-2, for detailed specifications and classes of equipment suitable for each exposure.

Lenses for protection against impact are required to withstand without shattering the impact of a $^7/_8$-in. steel ball dropped from a height of 50 in. The research report, *Plastic Eye Protectors*, released by the National Safety Council, indicates that most plastics had an impact resistance comparable to that of hardened glass. However, there is a possibility of optical distortion due to surface scratches on the comparatively soft plastic.

Most industrial companies furnish their employees, without charge, plano goggles of the spectacle or eye-shield type. A few companies provide for complete eye examinations and furnish prescription-ground hardened glass goggles, but the majority of companies assume only a portion of the extra cost of prescription goggles.

Some companies report that a rule requiring *all* employees to wear eye protection is a good investment; others limit the use of goggles to certain hazardous areas or to specific operations.

Plastic face shields give an excellent sense of security, particularly when worn over regular eye protectors. They are used on spot welding operations, babbitting, and in handling corrosive chemicals where full protection of the face is desired.

RESPIRATORS. Where local exhaust cannot be employed to provide respiratory protection, gas masks, hose masks, and respirators protect against harmful fumes, mists, gas, vapors, and dusts. Respirators should be of a type approved by the U. S. Bureau of Mines. These are the types of respiratory equipment:

Air-supplied suits for complete protection of the body in atmospheres that are extremely corrosive to the skin.

Hose masks with complete face piece, used where there is an inadequate supply of oxygen or a dangerous concentration of dust, vapor, or gas. The large-diameter, flexible hose permits breathing even though the hand- or motor-operated, low-pressure pump is not functioning.

Oxygen-breathing apparatus, which provides a self-contained oxygen or compressed air tank, or oxygen-generating mechanism, for work in atmospheres deficient in oxygen where mobility is required.

Air-line respirators consisting of a small mouth and nosepiece connected to a small airline which supplies air for work in atmospheres that are not immediately hazardous to life.

Gas masks and cartridge respirators, for protection against solvent vapors and injurious gases provided there is an adequate supply of oxygen. The chemical canister or cartridge is identified by different colors for different hazards:

Black—Organic vapors.
White—Acid gases.
Yellow—Organic vapors and acid gases.
Green—Ammonia.

Brown—Organic vapors, acids, gases, and ammonia.

Red—All industrial gases, including carbon monoxide, smoke, and fumes.

White with green stripes—Hydrocyanic acid gas.

White with yellow stripes—Chlorine.

Such canisters are approved by the U. S. Bureau of Mines for use in concentrations up to 2% of both gases and vapors.

Filter respirators for protection against nontoxic dusts, including silica, toxic dusts, and fumes. They contain no chemical and therefore are of no value if there is an oxygen deficiency, injurious gases, or solvent vapors.

Abrasive blasting hoods or complete helmets and hoods provided with a window and supplied by air at low pressure. Such equipment is commonly used by sand blasters.

HEAD AND EYE PROTECTION. Hard hats, commonly used in the construction, mining, shipbuilding, quarrying, and meat-packing industries are built of aluminum or lightweight composition which withstands a considerable impact without possibility of injury to the wearer.

Hair protection for women is provided better by safety caps with a high crown and stiff peak than by bandanas, turbans, and hair nets.

Acid hoods of rubber or synthetic resin protect the entire head and shoulders against splashing and dripping of acids and caustics. In such exposures, rubber gloves, aprons, and boots are also called for.

FOOT AND LEG PROTECTION. Work shoes with a built-in, steel toe cap capable of supporting a static load of 2500 lb or the impact of a 50-lb weight dropped 1 ft are readily available at most retail stores at prices comparable to good-grade work shoes. Either such shoes or steel toe caps which fit over ordinary shoes should be worn when handling heavy objects.

Leggings of chrome leather, asbestos, or flame-resistant canvas are necessary for foundry workers and others exposed to splashes of molten metal and sparks.

HAND PROTECTION. Hand leathers, pads, or gloves protect the worker against cuts, abrasions, and puncture wounds when handling rough lumber, sheet metal, castings, and other material which might injure the hands. Rubber gloves must be worn when handling corrosive chemicals and for work on high-voltage electrical equipment.

20. FIRE PREVENTION AND PROTECTION

MATCHES, improperly used, and smoking are outstanding fire causes according to the National Fire Protection Association. Smoking and the use of open flames should, of course, be absolutely prohibited in hazardous areas such as woodworking shops, textile mills, certain chemical plants, and wherever flammable liquids, vapors, or gases may be present. If smoking is prohibited in a plant or in certain departments, employees should be granted permission to smoke in designated fire-safe areas.

OTHER FIRE CAUSES are overheated bearings, belt friction, insufficient insulation for stoves, heaters, and electrical appliances, spontaneous ignition, static electricity, and defective electric wiring.

GOOD PLANT HOUSEKEEPING is essential to fire prevention as well as accident prevention. A regular system of rubbish and waste disposal should be set up, and approved type containers should be provided for the storage and disposal of all combustible material and rubbish.

FIRE-SAFE CONSTRUCTION. A building constructed of "fireproof" materials does not necessarily protect the occupants. Adequate fire exits should be provided, should not be blocked, and should be identified by fully visible exit signs and lights. Fire-alarm systems, adequate fire protection equipment, and a carefully prepared plan for evacuating occupants in an emergency are necessary adjuncts to safe construction.

Both commercial and home-made solutions are available for flameproofing fabrics. Wood may be made more fire resistant by coating or impregnating it with chemical solutions.

AUTOMATIC WATER SPRINKLING SYSTEMS are recognized as the best means of extinguishing fires. Systems are the wet, dry, thermostatically operated, and open. The wet system must be protected against freezing and also must be carefully inspected and maintained to insure operation in an emergency. Sprinkler heads are commonly rated at 155 to 165 degrees, with others rated up to 500 F.

FOAM AND CARBON DIOXIDE systems may be installed where water sprinklers cannot be used. Water spray and fog nozzles provide good protection against flammable liquids and may even be used safely by experts on live electrical equipment such as transformer banks.

PORTABLE FIRE EXTINGUISHERS. The right type of portable extinguishers should be available for each of the three classes of fires.

Class A (wood, paper, rubbish, etc.). Soda-acid, water pump, water and gas cartridge, foam.

Class B (oil, gasoline, paints, etc.). Foam, loaded stream, carbon dioxide, vaporizing liquids, dry chemical.

Class C (live electrical equipment). Carbon dioxide, vaporizing liquid, dry chemical.

Water base extinguishers must be protected against freezing and cannot be used on electrical equipment because of the shock hazard.

21. ACCIDENT REPORTING

These types of disabling injury are included in the computation of accident rates: death, permanent total disability, permanent partial disability, temporary total disability (commonly called a *lost-time accident*).

THE ACCIDENT FREQUENCY RATE is the number of disabling injuries per million man-hours worked. The average frequency rate for all industries in recent years has been between 10 and 15. Certain industries, formerly considered hazardous, have established frequency rates of considerably less than 10.

THE ACCIDENT SEVERITY RATE is based on the number of days of disability plus standard time charge for deaths, permanent total, and permanent partial disabilities. The severity rate is stated as the number of days of disability, including such time charges, per thousand man-hours worked. The average severity rate for all industries is approximately one.

22. TRAINING AND SUPERVISION

SELECTION AND TRAINING of a new employee requires an accurate knowledge of the employee's physical and mental abilities and of the job. Physical examinations should be for correct job placement, rather than for "weeding out." Many large companies also give aptitude tests, to place new employees better.

Safety training starts with the interview of the applicant and continues until he leaves the company. It is handled as a part of production training, with the foreman constantly impressing the employee with the importance of working safely.

Successful training includes: (1) Planning and preparing for a safe job. (2) Telling and showing the employee how to do the job safely. (3) Supervising and encouraging the employee while he does the job. (4) Following up frequently to check unsafe practices.

THE FOREMAN is the key man in accident prevention. He is in direct contact with the causes of accidents at the job level. He can discover and remove unsafe conditions before they cause injury, and he represents top management in carrying out company policies.

The principal safety duties of the foreman are: (1) To make safety an integral part of each job and to instruct new and old employees in the right way to do the job. (2) To detect and correct both unsafe conditions and unsafe acts in his department. (3) To insist on prompt reporting of injuries and to furnish accident reports to management. (4) To set a good example for his employees.

The foreman, who often must first be convinced of the need for safety, should receive special training in the more technical phases of machine guarding, personal protective equipment, and health hazards, and in the technique of training his employees. Special aids for training the foremen and for his use in training employees are available from many sources.

INSPECTION SYSTEMS vary but always require planning to avoid wasted time and effort. A thorough and very complete appraisal of physical hazards is necessary at the start of the program. Often very complete inspections are made annually to furnish the management with an accurate picture of the progress made during the year so that long-range plans may be made for the removal of hazards. Such inspections may be for fire hazards, fire equipment, housekeeping, machine guarding, and the like. Less detailed inspections and reports are often made monthly.

Inspections also can serve to educate employees and supervisors, particularly if made by a rotating committee. Then the forms or check lists are of the "reminder" type and are valuable for checking progress over daily, weekly, or monthly intervals.

Inspection forms must be appropriate for the type of inspection desired and should be arranged so that progress on recommendations can be easily checked. It is extremely important that action be taken promptly on all recommendations and that necessary delays in compliance be explained.

The forms may give a running or continuous report of plant changes or furnish information on new processes or equipment. The common fault of reporting unsafe physical conditions and overlooking unsafe acts should be guarded against.

Inspections may be made by specially trained men such as boiler or elevator insurance inspectors, by the company safety engineer, by plant maintenance men, and by special committees.

23. SOURCES OF INFORMATION

NATIONAL SAFETY COUNCIL, 20 North Wacker Drive, Chicago 6, Ill., is a nonprofit, nonpolitical association, comprising thousands of industrial and other members who work cooperatively for the solution of their common accident problems. The Council has over twenty separate industrial sections and engages also in traffic, farm, school, and home safety work. It provides statistical, consultation, and library service as well as "Safe Practices" pamphlets, magazines, posters, and other publications; it conducts training courses, research, and has numerous local chapters and affiliated local safety councils.

AMERICAN SOCIETY OF SAFETY ENGINEERS, 20 North Wacker Drive, Chicago 6, Ill., is composed of several thousand professional safety engineers with chapters located in every section of the United States. It sponsors safety codes and research projects.

LOCAL SAFETY COUNCILS are affiliated with the National Safety Council and offer a localized consultation service, facilities for exchange of information, and joint educational programs.

AMERICAN STANDARDS ASSOCIATION, 70 E. 45 St., New York 17, N. Y., is a federation of national associations and government departments dealing with standardization. Through its member bodies it formulates standard codes which are often used as the basis for city and state health and safety codes.

NATIONAL FIRE PROTECTION ASSOCIATION, 60 Batterymarch St., Boston 10, Mass., is the national authority on fire prevention and protection. It publishes the Crosby-Fiske-Forster *Handbook of Fire Protection*, the *Quarterly*, technical reports, numerous posters, and other material.

NATIONAL BOARD OF FIRE UNDERWRITERS, 85 John St., New York 7, N. Y., maintained by the stock fire-insurance companies, provides engineering, statistical, and educational information, aids in the promotion of safe building construction, and publishes numerous technical pamphlets.

ASSOCIATION OF CASUALTY AND SURETY COMPANIES, 60 John St., New York 7, N. Y., represents the stock casualty companies. It publishes numerous safety booklets and serves as a clearing house on accident prevention information for its members.

AMERICAN MUTUAL ALLIANCE, 919 North Michigan Ave., Chicago, Ill., represents the mutual casualty companies and provides similar service.

OTHER SOURCES OF INFORMATION. Insurance carriers, state and federal agencies, consulting safety engineers, and safety-equipment manufacturers are in a position to furnish helpful materials and consultation service.

DUST COLLECTION

By R. B. Foley

24. CHARACTERISTICS OF DUSTS

CLASSIFICATION. Solid particulate matter in air is generally classified as dusts, fumes, or smoke.

Dusts are mechanical dispersoids formed by the reduction of larger masses into fine particles by such processes as grinding, crushing, and drilling.

Fumes are condensed dispersoids formed by condensation or sublimation from the vapor phase.

Smoke is the term generally applied to the special form of fumes produced by combustion.

Size of such particles is usually expressed in terms of the particle diameter in microns. A micron equals $^1/_{1000}$ mm or approximately $^1/_{25,000}$ in.

Dusts are usually particles 1 micron and larger in diameter, fumes range from 0.10 to 1.0 micron in size, and smoke particles vary from 0.001 to 0.25 micron. Fumes very often agglomerate into larger particles which can be considered dusts in their behavior and treatment.

PHYSICAL CHARACTERISTICS OF DUSTS. The important physical properties of dust particles which affect their behavior in air or any other fluid are size, shape, and weight. Although it has been a common practice to express the behavior of dust particles in an air stream as a function of their size or diameter, the other two properties are of equal importance. The weight which must be considered is the true density, or specific gravity, of the particle; not the bulk density of the material.

MEASUREMENT OF DUST CHARACTERISTICS. Screens. The size of dust particles is most commonly measured by grading with standard screens or sieves. These screens are made of woven wire cloth with openings of definite and uniform sizes. The mesh size equals the number of wires per linear inch, so the number of openings per square inch equals the square of the mesh number. The Tyler Standard Screen Scale consists of screens in which the size of the openings vary in the fixed ratio of the square root of 2 or 1.414. Table 1 illustrates the proportions of common screens. The finest standard screen, however, has 400 meshes per inch, and many industrial dusts consist principally of particles which will pass through this screen.

Table 1. Properties of Common Screens

Screen mesh	20	40	60	80	100	150	200	325	400
Width of mesh opening, inches	0.0328	0.0150	0.0097	0.0069	0.0058	0.0041	0.0029	0.0017	0.001425
Approximate microns across net opening	833	380	246	175	147	104	74	43	36

Microscopic Examination. The measurement of particle size by means of microscopic examination is one of the simplest methods for measuring subsieve-sized particles. It also provides a means for determining the shape of dust particles. Since most dust particles are very irregular in shape, the determination of the average linear dimension is rather difficult. This method is also limited by the difficulties involved in dispersing a truly typical sample within the small field which can be studied under a high-powered microscope.

Elutriation and Sedimentation. The two methods now most frequently used for analyzing subsieve dusts depend upon their aerodynamic characteristics. They are the elutriation and sedimentation methods. Since both these methods involve the determination of the terminal velocities of the particle, they measure the combined effect of all three of their physical properties upon their behavior in air or any fluid. The terminal velocity of a dust particle is the ultimate velocity which it will obtain when falling through a given quiescent fluid. That is, it is the velocity at which the resistance of the fluid to the motion of the particle equals the gravitation force on it, so that acceleration ceases and the velocity becomes constant.

In the sedimentation methods, the terminal velocity, or rate of fall, is measured in a quiescent fluid, usually a liquid. The analysis is made by determining the percentage, by weight, of the sample which falls through a certain distance in various time intervals.

Elutriation methods are the reverse of sedimentation but are based on the same laws and thus measure the same characteristics. The upward speed of a fluid column which will just sustain a particle, so that it will neither rise nor fall, is equal to the terminal velocity which the particle would obtain in free fall in the same fluid. In elutriation, the analysis is made by carrying upward, in a fluid stream, those particles which have a terminal velocity less than the upward velocity of the fluid. Air and water are the fluids most commonly used. Regardless of the fluid used for the analysis, terminal velocity is generally expressed in terms of the particle velocity in standard air, since most dusts are contained or handled in air.

Although it has been quite common practice to express the results of analyses made by the sedimentation or elutriation methods in terms of particle diameters in microns, the transition from terminal velocity is usually based on the assumption that the particles are spheres of uniform density. Since most dusts are very irregular in shape, and a heterogeneous mixture of materials of different specific gravities, these assumptions are not usually accurate. The relationship between terminal velocity and particle size is expressed by Stokes' law:

$$V_m = \frac{\alpha_v}{K} g d^2 \left(\frac{\rho - \rho_0}{\mu} \right) \tag{1}$$

when V_m = terminal velocity of the particle; d = diameter of the particle; ρ = density of the particle; ρ_0 = density of the fluid medium; μ = viscosity of the fluid medium; g = acceleration due to gravity; α_v = a constant, depending on the shape of the particle, and such that $\alpha_v d^3$ measures the volume of the particle; and K = a constant which varies as the particle shape and is 3π for spheres.

For solid spherical particles the particle diameter in microns when cgs units are used is:

$$d = \sqrt{\frac{18\mu V_m \times 10^8}{g(\rho - \rho_0)}} \qquad (2)$$

Figure 1 is a chart giving this relationship for solid spherical particles of various specific gravities.

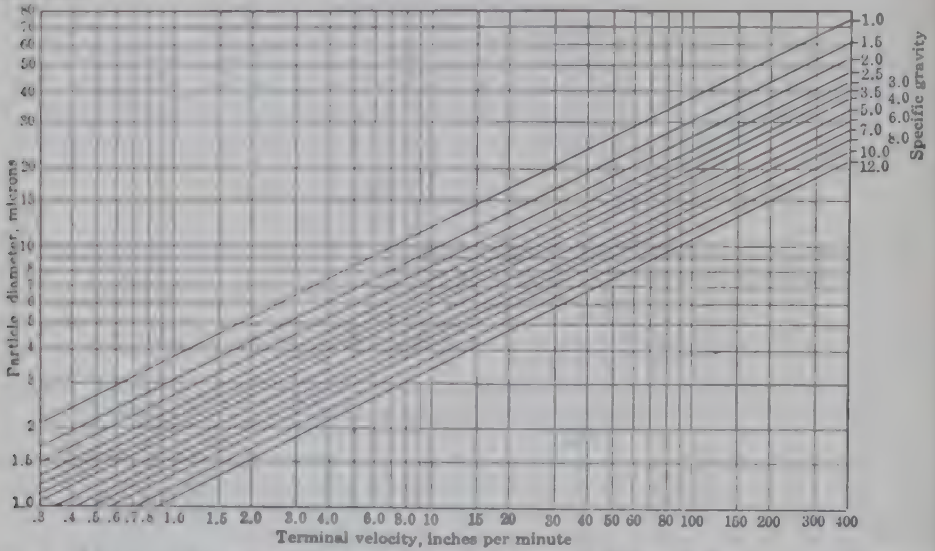

FIG. 1. Relationship between particle size and terminal velocity for solid spherical particles, based on Stokes' law.

Within the range generally encountered in industrial dusts, the cumulative analysis in terms of terminal velocity is usually a straight line when plotted on log-probability scales. Figure 2 illustrates such plots of several common dusts.

Miscellaneous Methods. There are several other methods used to measure average particle size, most of them dependent on the surface area of the particles. Those falling in this category are the photoelectric or turbidimetric methods, the permeability method, and the adsorption methods. Although the results obtained by these methods are of value in determining properties that affect chemical reactions, they do not measure the physical characteristics that affect their behavior in an air stream.

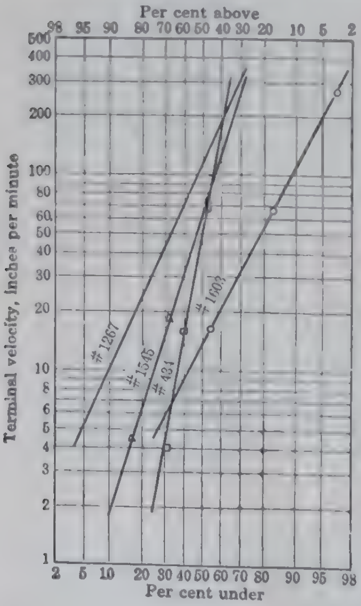

FIG. 2. Cumulative analyses of typical dusts, plotted in terms of terminal velocity on log-probability scales.

TYPES OF DUSTS. Dusts may also be classified in groups determined by the types of material from which they are produced.

Toxic Dusts. In addition to dusts produced from poisonous materials, these include also dusts that are injurious to health in their finely divided state, although the material from which they are formed is not harmful. Dusts that contain a large percentage of free silica are of this type since they produce silicosis. Particles less than 10 microns in size appear to be most dangerous in these types of dusts because they are not filtered out in the nasal or throat passages

Explosive Dusts. All fine inflammable dusts are explosive when present in air at certain concentrations. At one time, only dusts produced from carbonaceous materials such as coal, grain, starch, sugar, and wood were considered explosive. Recent experience and laboratory tests, however, have shown that many metallic and plastic dusts may form explosive mixtures with air. Zirconium, magnesium, aluminum, and titanium are among the most explosive of the metal powders, whereas many of the dusts from synthetic resins, especially those of the phenolic type, must also be included in this group. Although generally dust concentrations below 10 grains per cubic foot of air are not explosive, tests have proved that very fine dust of the more inflammable types will form explosive mixtures at much lower concentrations. When dust of this type is handled it is very important to eliminate all possible sources of ignition. All metal parts should be grounded, and the rotating parts of all machinery, such as fans, should be made of sparkproof material.

Nuisance Dust. A large number of industrial dusts fall in this group. Although they are not directly injurious to health or safety, their control and collection result in improved working conditions, lower maintenance, longer equipment life, and improved public relations. In many cases the dust collected is of no value. However, research has led to the discovery of uses for some of these dusts which pay for at least a portion of the cost of collecting and handling them.

Products. In many industries the final product, or some of its component parts, are handled in a powdered form and their separation from air streams is an important part of the process. Recent developments in powder metallurgy and in spray-drying processes have added many materials to this group.

By-products. Many valuable by-products are salvaged in the form of dusts or powders, and, in some cases, dusts which were formerly considered a nuisance have become as valuable as the original product. Powdered catalysts might also be included in this group, since although not a part of the final product their control is essential to its processing.

25. TYPES OF DUST COLLECTORS

GRAVITATIONAL. Settling chambers, which are the oldest and simplest form of dust separators, depend on gravitational forces. The velocity of the air or gas is reduced to the point where the dust particles will settle out of the air stream. Figure 1 illustrates the low velocities necessary to settle out the finer dust particles. Turbulence and eddy currents also tend to suspend particles that would theoretically settle out, and the size of a unit that would be required to give velocities in the streamlined flow region would be prohibitive.

To be effective, not only must the cross-sectional area be large enough to give a low velocity, but the length must be great enough to prevent the particles from being carried to the outlet by their inertial force. Although relatively inefficient, settling chambers are sometimes sufficient when the dust is coarse and heavy. Their principal use, however, is as preliminary separators, when the concentration is high, to reduce the dust loading before the air or gas passes on to a more efficient type of dust collector. They are also sometimes used to obtain a rough preliminary grading of the material.

INERTIAL. Baffle types of inertial separators are a modification of the settling chamber in which a baffle or a series of baffles is employed to cause a sudden change of direction in the dust-laden air stream and thus throw out the dust particles due to their greater inertia. Although they can be designed to occupy somewhat less space than settling chambers without baffles, they are generally used for similar applications. Care must be taken in the design and location of the baffles so that the dust is not re-entrained in the airstream because of the eddies and turbulence set up by the baffles.

CENTRIFUGAL. In centrifugal-type collectors, radial acceleration or centrifugal force is utilized to separate the dust particles from the air or gas stream. The centrifugal settling velocity, which is the outward or radial velocity of a dust particle in a centrifugal collector, can be expressed by the following equation for particles within the Stokes' law range:

$$V_c = \frac{\alpha_0}{K} d^2 \left(\frac{\rho - \rho_0}{\mu}\right) \frac{V_t^2}{R} \qquad (3)$$

when V_c = centrifugal settling velocity, V_t = tangential velocity of the particle, and R = radius of the circular path of the particle.

A comparison of this equation with eq. 1 for the terminal velocity, V_m, shows that $V_c = V_m \times V_t^2/Rg$. The factor V_t^2/Rg, called the "separation factor," is a measure of the increase in separation velocity obtained by centrifugal action as against gravitational action.

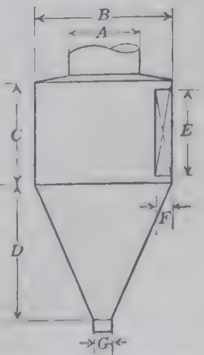

FIG. 3. Low velocity cyclone

Low-velocity Cyclones. The most familiar type of centrifugal collector is the common or low-velocity cyclone shown in Fig. 3. In this type of cyclone, the dust-laden air enters the cylindrical body of dust is often settled out in a chamber ahead of the screens. Figure 6 shows a typical cross section of this type of filter.

The velocity through the cloth depends on the type and concentration of the dust, as well as on the efficiency and power requirements. Although the capacity of cloth filters varies from $^1/_2$ to 10 cu ft per min per square foot of cloth area, for most industrial application the maximum should be 4 cu ft per min. With most materials, lower velocities through the cloth result in better collection efficiency, lower maintenance and operating costs, and longer life.

Although at the design velocities the resistance through the cloth is quite low when the cloth is clean, it increases as the dust builds up on the surface. The efficiency of collection is somewhat higher after the pores of the cloth have filled with dust; however, the reduction in air volume as the resistance increases necessitates cleaning or shaking at regular intervals. The efficiency of properly designed cloth filters is generally very good, and, where the dust is not toxic, the cleaned air can sometimes be returned to the building.

When the concentrations are high, centrifugal-type collectors are often used as primary separators ahead of cloth filter, to reduce the frequency of cleaning and increase the life of the cloth. In addition to the limitation of gas temperature, cloth filters are not suitable when there is moisture in the gases, or with some types of dust which tend to matt on the cloth surface and prevent the normal flow of air.

Impingement-type filters are made in a great many forms but they usually consist of metal or paper channels, or loosely packed fibers such as steel or glass wool, coated with a viscous material. The air is forced to take a tortuous path through the filter, and the dust is impinged against the surfaces where it is retained by the viscous coating. As the dust builds up on the surfaces, the resistance to flow increases and the filter must be replaced or cleaned.

Since this type of filter is suitable only for low concentrations of dusts, its industrial application is usually as a final cleaner following one of the other types of dust collectors, or when only normally air-borne dust must be removed from the air. There are several automatic types that are self-cleaning. In these oil is generally the viscous coating. Either the oil is flushed over the filtering medium, or the medium is rotated slowly as it passes through a bath of oil.

WASHERS. Many dusts, which are either soluble or wettable in water, can be efficiently washed from the air stream. In order to be effective cleaners, washers must provide a large area of water surface in intimate contact with the dust-laden air. Although there are many designs of air or gas washers, they all provide this surface area either by the use of sprays, wetted impingement surfaces, or a combination of the two.

The wettability of the dust, desirability of handling the dust in a sludge form, and the available water supply are factors which must be considered in connection with washer-type collectors. Unless an inexpensive water supply and adequate facilities for disposal of the contaminated water are available, settling tanks are usually used and the water is recirculated through the collector. A conveyor is sometimes installed in the bottom of the settling tank for automatic removal of the sludge. When finely atomizing spray nozzles are used, however, it is important that the water be clean enough to prevent plugging of the nozzles.

Dusts that are highly inflammable or explosive when dry, such as magnesium dust, can be handled most safely in wet washers. Some dusts and gases, however, although easily cleaned in this type of collector, form corrosive liquids which necessitate construction of special materials to resist the corrosion. Although many of these washers clean the air sufficiently to allow its recirculation in the building, the intimate contact of the air and water necessary for maximum cleaning efficiency also produces nearly complete saturation so that the effect of increased humidity must always be considered.

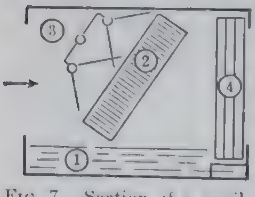

FIG. 7. Section of a capillary air washer, showing (1) tank, (2) cell of fine glass fibers, (3) low head distributing sprays, and (4) metal moisture eliminators.

Spray-type Washers. The simplest of this type is the common air washer, which consists of a bank of spray nozzles located above a tank and followed by a series of baffles or eliminator plates that remove entrained moisture. Washers of this type use 3 to 15 gal of water per 1000 cu ft of air, depending on the type of dust and temperature of the air. The air velocity is low, usually about 500 ft per min so that the resistance to flow is generally less than $^1/_2$ in. water gage.

The simple spray type is suitable only for light dust concentrations. In a newer design of air washer the water is sprayed against the face of a cell filled with fine glass fibers, oriented to form a multitude of minute wetted air passages. Since they provide a large area of wetted surface, fine atomization is not necessary, and coarse low-head spray nozzles can be used

Three to 8 gal of water per 1000 cu ft per min is normally used, and, with an air velocity of 400 ft per min, the resistance is 0.4 to 0.5 in. water gage. This type of unit is quite efficient in the elimination of wettable dust present in moderate concentrations. Figure 7 illustrates the arrangement of its component parts.

Scrubbers are washers in which the dust is impinged against a large area of wetted scrubbing surface. In its simplest form the water flows over a distributor plate and down over a series of impingement plates countercurrent to the flow of dust-laden air or gas. In some units of this type, flowing water or sprays are used in combination with centrifugal action in the gases to throw both the dust and water against wetted surfaces. In the packed scrubber tower, the tower is filled with solid hurdles such as grids, terra cotta shapes, or coarse coke. The water quantities used depend on the type of dust, dust concentration, and gas temperature. Velocities and resistance to flow are generally considerably higher than in the spray type of units.

In several popular types of wet scrubbers, such as the one shown in Fig. 8, a fine spray or water curtain is produced, without the use of nozzles and a pump, by impinging the air at a high velocity against the surface of the water in the tank. The air passes through the water curtain, and the spray and air are usually impinged against baffle plates. Although the resistance to flow is higher than in units that use nozzle sprays, the only make-up water required is that lost by evaporation. In another type a high-speed rotor carries the water from the tank into the air stream.

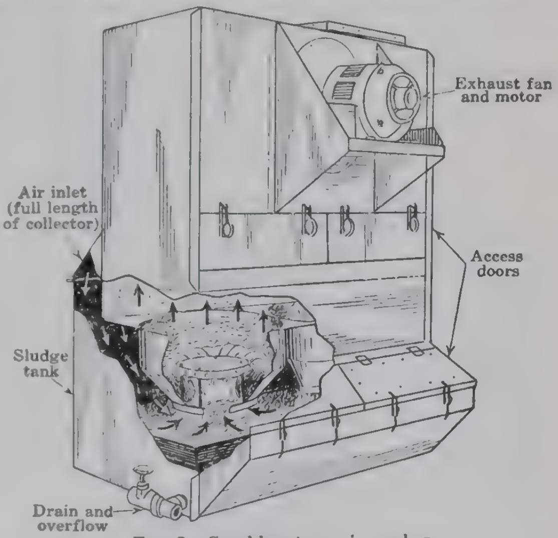

Fig. 8. Scrubber type air washer.

Froth-type collectors are generally a combination type of washer. After the air has been sprayed or scrubbed by one of the foregoing methods the partially saturated air is forced through some type of nozzles or orifices into a liquid bath. The liquid bath is usually water to which some wetting agent, such as flotation oil, has been added to reduce the surface tension and produce a finer froth. After leaving the surface of the bath the air and entrained liquid impinges against baffle plates. Although the cleaning efficiency of these froth-type collectors is very good, the inherent resistance through the collector is high; and the velocity through the liquid bath must not be too great or the pressure drop will be excessive.

Disintegrators. In the disintegrator type of gas washer the liquid is dispersed, and the air and liquid intimately mixed, mechanically. This is accomplished by a series of rotating cages, which are usually turned by the same shaft that drives the fan impeller that moves the gas through the unit. In some designs the rotating cages are alternated between similar stationary cages. Disintegrators are effective even on very fine particles. However, because of their high power requirements, they are generally used only on hot gases, such as blast furnace gas, where both a cooling and a thorough cleaning are desired.

ELECTROSTATIC PRECIPITATORS. In electrostatic precipitators the air or gas is passed through an electrostatic field produced by a high-voltage d-c discharge between two sets of electrodes. The dust particles become ionized and are attracted to the collecting electrodes.

Electric precipitators are capable of very high collection efficiencies with very fine dusts when properly designed and operated for the particular application. Since the collection efficiency is a function of the time that the gas remains in the active field, precipitators designed for maximum efficiency must be large in both cross-sectional area and length. In any case the velocity of the gases must be low enough so that the precipitated dust is not redispersed in the gas stream. Gas velocities usually range from 300 to 600 ft per min, and consequently the resistance to gas flow is low.

Uniform gas distribution is essential to proper operation, and straightening vanes or perforated distributor plates are often used at the inlet of the precipitator. The surface conductivity of the dust particles is an important factor in their precipitation, and with some dry nonconductive dusts the gas and dust are conditioned by introducing some conductive wetting agent, such as water or steam. Since electrical precipitators are most efficient with low dust concentrations, and are effective on even the finest particles, they are often used in conjunction with the centrifugal type of collectors for the final cleaning.

The two methods of electrical precipitation are represented by the single-stage and double-stage types.

Single-stage Type. The single-stage type, commonly known as the Cottrell system of electrical precipitation, is used most generally for industrial applications. The particles are charged and collected between the same set of electrodes, and the discharge is maintained throughout the unit.

In order to obtain the corona discharge, the discharge electrodes must either be small or have sharp edges. Either fine wires or twisted square steel rods are generally used. There are several designs of collecting electrodes, and the type used depends on the application. In the earlier designs they consisted of vertical pipes, 3 to 12 in. in diameter and 5 to 15 ft long. These are now most commonly used in the wet-type precipitators, whereas plate-type collecting electrodes are generally used in the dry precipitators.

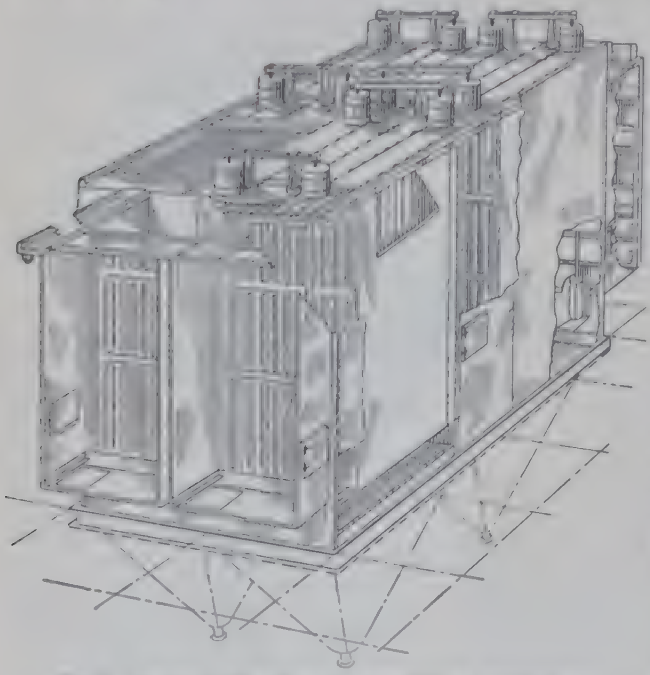

FIG. 9. Single-voltage plate type electrostatic precipitator.

The plate type consists of a series of parallel plates between which the discharge electrodes are suspended. There are several modifications of the plate type, such as steel plates that are sometimes corrugated, rod curtains that consist of a number of small rods or pipes hung close together, concrete plates with the conductor rods embedded in them, perforated or dual plate type consisting of perforated plates welded up in the form of narrow boxes with perforated sides, and pocket electrodes in which the precipitated dust is trapped in V-shaped pockets. When the plate-type electrodes are used the spacing between the opposing electrodes is ordinarily 3 to 6 in.

The electrodes are usually assembled in cells or sections and one or more cells are used in series, depending on the degree of cleaning desired. Figure 9 shows a single-stage plate-type unit.

Since the dust particles are deposited on the collecting electrodes, some method must be provided for removing them from the surface. In the wet precipitator the gas flow is upward, and water flows downward over the collecting surface to carry off the precipitated particles. In the dry type of units the gas flow may be either vertical or horizontal, and the dust is removed from the plates by scraping or rapping them. Compressed air or motor-driven rappers are most commonly used, and the frequency and duration of the rapping periods depends on the type and concentration of the dust.

The electrical equipment necessary to produce the high-voltage direct current consists of a transformer and either a mechanical or an electronic rectifier. The voltages most commonly used range from 60,000 to 100,000 volts. The mechanical rectifier is usually driven by a synchronous motor, whereas the electronic type consists of a group of electron tubes arranged to give full-wave rectification. Either type of rectifier gives equally satisfactory precipitation, and, although the electronic type requires less space, the control equipment required for its operation is somewhat more complicated. The power consumed is about the same for either type, and, although the voltage is high, the current is very low so that the power consumption is only 0.5 to 1 kwhr per 100,000 cu ft of gas cleaned.

Double-stage type electric precipitators consist of units in which a pre-ionization stage is used ahead of the collecting stage. Figure 10 illustrates the principle of operation of this type of precipitator. The corona discharge takes place in the first or ionizing stage, and the dust is precipitated on alternating, oppositely charged, plates in the second or collecting stage.

Lower voltages are used, usually 10,000 to 14,000 volts in the ionizing section and 5000 to 7000 volts on the collecting plates. With these lower voltages the plate spacing must be considerably closer, usually $^5/_{16}$ to $^1/_2$ in. As a result of this close spacing, this type of precipitator is generally used only when the dust concentration is low. High concentrations would require too frequent cleaning to prevent the dust from building up on the plates to a point where the current would arc-over.

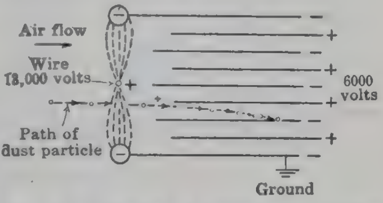

Fig. 10. Principle of operation of double-voltage type electrostatic precipitator.

The collecting plates, which are usually coated with a viscous material to hold the dust, are contained in cells that can easily be removed for cleaning by washing off the plates. Each cell handles 600 to 750 cu ft per min.

Provision is made in some units for automatically washing and recoating the plates, without removing the cells, by the use of movable spray nozzles. The cells being cleaned, however, must be disconnected electrically and dampered off from the gas flow. In one type of unit the cleaning plates are continuously rotated through a bath of viscous fluid for automatic cleaning.

Electronic rectifiers are used with this type of precipitator, and the power requirements are of the order of 0.01 to 0.02 kw per 1000 cu ft per min. The gas velocity is 300 to 400 ft per min so that the resistance to flow is only a few tenths of an inch water gage. Since the voltages are much lower than in the single-stage type, the ozone produced is much less. Although the double-stage precipitator is suitable only for use with low dust concentrations, it is most satisfactory for cleaning air to be used for ventilation in an occupied space since its cleaning efficiency is very high even for the finest particles, and the ozone produced is very low.

26. DUST-COLLECTOR SYSTEMS

FACTORS INFLUENCING DESIGN AND REQUIREMENTS. The most important factors that influence the design and requirements of a dust-collection system are those that determine the need for the system.

Improvement of working conditions is probably one of the most common reasons for the installation of a dust-collector system, and its importance should not be underestimated. In any process where dust is produced, the elimination or control of the dust pays dividends in improved efficiency of both workmen and machines. The control of the dust at its source is the important requirement, and the best design is the one that will accomplish this control with minimum amount of air.

Health of workers is the most important reason for the control of dusts, and, in the design of systems where health conditions are involved, adequate design must take precedence over economic considerations.

State laws, which usually govern the requirements of such systems, should be consulted when the design is being considered. For example, the maximum allowable concentration of such poisonous dusts as lead dust in some states is 0.15 mg per cu meter of air. Table 3, which gives the probable safe limits for several harmful types of dusts in millions of particles per cubic foot of air, is based on the light field microscope counting technique.

Table 3. Probable Safe Limits for Several Harmful Dusts in Million Particles per Cubic Foot

Type of Dust	
Asbestos dust	5
High silica dust (100 to 50% free silica)	5
Medium silica dust (50 to 5%)	20
Low silica dust (5 to 0%)	50
Marble	20
Granite	10
Silver	12

Nuisance Elimination. In addition to removing the dust from the working area, dust-collection systems are needed to prevent dust's being a nuisance to the surrounding neighborhood and general public. The conditions necessary to eliminate this type of nuisance often govern the degree of cleaning and type of dust collector required.

Recovery of material, which is either the product or a by-product of the dust-producing process, is the purpose of many dust-collector systems. The form in which the material can be utilized influences the design and type of dust collector, and the value of the material governs the requirements regarding collection efficiency.

TYPES OF SYSTEMS. Central exhaust systems are the type most commonly used in industry. In this type of system the hoods, or enclosures, at the dust sources are connected by branch pipes to the main duct or header, which conveys the air and dust to the dust collector and fan. The design of such systems is often specified by state laws and codes, and the general design data given here should be checked to be sure they conform with local regulations. In general, the requirements of the central exhaust system are positive control of the dust at its source, adequate conveying to a safe and convenient point for collection and disposal, and a collection efficiency sufficient to eliminate any hazard or nuisance. The planing mill exhaust system shown in Fig. 11 is a typical example of this type of system.

Hood design is of primary importance since it is here that the dust is brought under control and removed from the working area. The first rule in hood design is to enclose the dust source as completely as possible without interfering with the work. This precaution not only makes it easier to control the dust but also reduces the quantity of air required. The design of the hood is usually governed by the type of work or the machine that is producing the dust and by the surrounding physical conditions. Figure 12 shows typical hoods for woodworking machines, and Fig. 13 illustrates the types used for grinding and buffing wheels. The hoods should be located so that the air movement is in the same direction as the particles are discharged by the machine. If any air currents are set up by the machine or process, they should also be in the same direction as the flow produced by the hood.

The velocity necessary at the face of the hood, or enclosure, depends on the type of dust being handled and the surrounding conditions. The face of the hood should be as close as possible to the dust source since, in general, the air velocity varies inversely with the square of the distance from the hood. When drafts, or opposing air currents, cannot be eliminated in the vicinity of the hood, the hood velocity must be enough higher to overcome them.

Generally, the air velocity should be high enough to pick up only the float dust which would escape or remain in suspension in the room air. When coarse heavy dust particles must be handled in the hood, provision should be made for settling out such particles as near the hood as possible so that they will not have to be conveyed in the piping system. Conveying of these coarser, heavy particles results in more rapid wear in the pipes and greater power requirements due to the higher conveying velocities that are necessary. Table 4 gives the air velocities required at the source to control various common types of dusts.

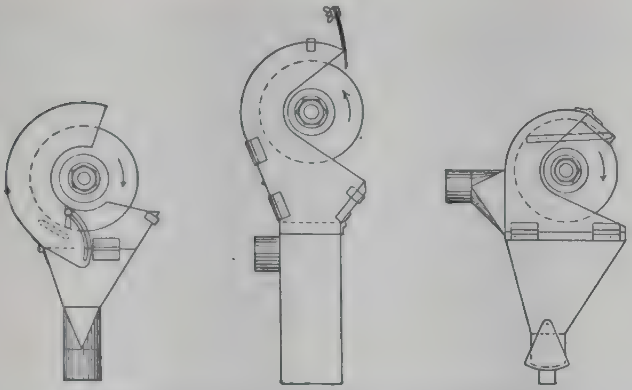

Fig. 13. Typical hoods for grinding and buffing wheels.

Table 4. Air Velocities for Controlling Various Types of Dust

Type of Dust or Fume	Process or Operation	Required Air Velocity, ft per min	
		At Dust Source	At Face of Hood
Granite	Hand pneumatic tool	200	....

Welding	Electric welding	200	....

Piping Design. The size of the branch pipe and the velocity of the air in the pipes must be adequate to convey the material picked up in the hood. Table 5 shows the size of the hood connections required for various types of woodworking machines.

Table 5. Sizes of Hood Connections for Woodworking Machinery

Type of Machine	Diameter of Pipe, in.	Type of Machine	Diameter of Pipe, in.
Matcher heads, each	5	Rip saws and resaws	
Sash and cabinet shaper, each head	4	Up to 14 in. diameter	4
Door tenoner	5	14 to 18 in. diameter	4 1/2
Sash tenoner	5	18 to 24 in. diameter	5
Door and sash sticker, each head	5	Cut-off saws not over 16 in. diameter	4
Blind slat sticker	5	Band saws	
Blind rail router	4	Up to 1 1/2 in. wide	4
Panel raiser, each head	4	1 1/2 to 3 in. wide	5
Sand drums		3 to 4 in. wide	6
24 in. long	5	4 to 6 in. wide	7
30 in. long	6	Buzz planers, moulders, planers, and all other machines having knives	
36 in. long	7	Up to 6 in. long	4
48 in. long	8	6 in. to 8 in. long	5
60 in. long	10	8 in. to 12 in. long	6
Belt sander		18 in. to 24 in. long	8
Up to 4 in. wide	4	24 in. to 30 in. long	9
8 to 12 in. wide	6	Floor sweep-up	6
Disk sander			
Up to 24 in. diameter	5		
24 to 36 in. diameter	6		

Although some state laws still specify the suction that should be maintained in the branch pipes from the hoods on grinding and buffing wheels, most of these laws and codes are being revised to give the requirements in terms of the volume of air that should be handled through the hood as this is a more correct measure of hood effectiveness. Table 6 gives the air volume in cubic feet per minute and size of pipe connections usually required for various sizes of grinding and buffing wheels.

Table 6. Branch Pipe Sizes and Air Volumes for Grinding Wheel Hoods

Wheel Size, in.		Branch Pipe Diameter, in.	Air Volume, cu ft/min
Diameter	Maximum Width		
Up to 9	1	3	225
9 to 18	3	4	400
10 to 24	4	5	600
24 to 30	5	6	900
30 to 36	6	7	1200

Table 7 gives the air velocities needed to convey various types of materials. Some laws and codes, however, set minimum velocities regardless of the type of dust handled.

Table 7. Air Velocities for Conveying Various Types of Materials

Material	Air Velocity, ft per min
Ashes or ground clinkers	6000–9000
Buffing lint, dry	2500–3500
Buffing lint, sticky	3000–4000
Cement	6000–9000
Coal, powdered	4000–5000
Cotton lint	1500–2000
Cotton seed	4000–6000
Flour	3500–6000
Fly ash	3000–4000
Foundry shakeout dust	3500–4500
Grain	4000–5000
Grain dust	2000–3000
Grinding dust	3500–4500
Lime	5000–7000
Metal turnings	4000–5000
Pulp chips, dried	4000–6000
Rags	4000–6000
Salt	6000–7500
Sand	6000–9000
Sand blast dust	3500–4000
Sawdust and shavings, dry	2000–3000
Sawdust and shavings, wet or green	3000–4000
Sugar	5000–7000
Wood chips	4000–5000
Wood flour, sander dust	2000–4000

It is worth while to give careful consideration to the design of the entry connection from the hoods to the branch pipes, and all points where there are turns or changes in section. Proper design at these points not only will prevent settling of the dust in the pipes but will also result in power savings from the lower resistance to flow. Table 8 gives the entry losses for the various designs of entry conditions for round pipes. Similar designs and entry losses from plenums or large hoods are given in Table 9.

In order to have a balanced system with the desired volume being drawn through each hood, it is necessary that the system be designed so that the total pressure in each branch is equal to the total pressure in the main header at the point where the branch enters the main. This means that the resistance of the system from the hood to the fan must be the same for all the connections on the same system. Usually the resistance of the system from the longest equivalent run to the fan is calculated, then the other branches are designed and sized for the same resistance. The main duct should be increased in area at each branch by an amount at least equal to the area of the branch. Some codes recommend an increase in area of 10 to 20% more than the branch pipe area, but when this method is used care must be taken that the velocity does not become too low for conveying the dust.

The piping is generally made of black or galvanized sheet steel. Round pipes are preferable to rectangular or square pipes. All joints should be made as smooth as possible,

Table 8. Entry Losses for Round Pipes in Percentage of Velocity Pressure at Diameter D

Type of Entry	Entry Loss, % of Velocity Pressure
 a	87
 b	48
 c	15
 d	2.5
 e	12
 f	65

and lapped joints should be lapped in the direction of air flow. All parts of the system should be made as free as possible from air leakage. The gage thickness of the piping material should be adequate for structural strength, and, when abrasive dusts are handled, heavier gages are required because of the abrasion on the pipes. Table 10 gives the minimum thickness that should be used for round pipes. Rectangular pipes should usually be made heavier for equal strength.

Elbows should be at least two gages heavier than that required for the pipes since they are subject to the greatest abrasion. Long radius elbows, with an inside or throat radius of at least two pipe diameters, are preferable and result in minimum resistance losses. The branch pipes should enter the main header at an angle of not more than 45 degrees, and an included angle of 30 degrees is preferable.

Table 9. Entry Losses from Plenums or Large Hoods

Type of Entry	Entry Loss, % of Velocity Pressure						
 *a*	256						
 *b*	47						
	∠α	5°	10°	15°	20°	25°	30°
 *c*		12.0	11.3	11.3	11.7	12.0	25.0
	R/D	0.15	0.25	0.50	0.75	1.00	1.25
 *d*		13.4	12.4	11.5	11.0	10.7	10.6

All horizontal pipes should be provided with hand holes for cleaning and inspection. These openings should have tight-fitting covers of a type that offer no obstruction on the inside of the pipe. With welded piping, flanged joints are ordinarily used every 10 or 15 ft to make installation and repair easy. The end of the main header should be capped with a tight-fitting but removable cap. Dampers or gates are sometimes provided to aid in balancing the system, but in a system handling dust they are unnecessary obstructions if the system is carefully designed.

Table 10. Gages of Metal for Round Pipes

Diameter of Pipe	U. S. Gage Number	
	For Abrasive Material	For Other Material
Up to 6 in.	20	24
6 to 8 in.	20	22
8 to 18 in.	18	20
18 to 32 in.	16	18
Over 32 in.	14	16

Dust-collector selection for the central exhaust system will depend upon the types of dust being handled and the degree of cleaning desired. Low-velocity cyclones are most commonly used for systems exhausting from woodworking machinery. High-velocity cyclones or cloth filters are generally used for exhausts from grinding operations and for foundry exhaust systems. If the dust is abrasive, the dust collector is usually placed ahead of the fan. However, in many systems handling such material as chips and sawdust, the material is handled through the fan and blown into the collector.

Fan Requirements. The volume of air and the total resistance of the system are the values which determine the capacity of the fan required for the dust-collector system. The resistance of the dust collector and its connections must be added to that of the hoods, branch pipes, and main header to determine the total resistance of the system. A fan of the desired capacity can then be selected from the capacity tables published by fan manufacturers. Centrifugal fans are usually used, and, when the fan is placed ahead of the dust collector, an impeller of the radial blade type is used since the material must be carried through the fan wheel.

Unit exhaust systems consist of combination fan and dust-collector units located at or near the dust source. They are frequently used at locations isolated from the central exhaust system or when there are only a few scattered sources of dust. Unit systems are also desirable when the dust is of an inflammable or explosive type, which should not be conveyed through a long piping system or mixed with other dusts in a central system. The dust collector and fan may be supported separately or they may be assembled as a unit in a single casing.

The combination type of unit, which is somewhat more portable, is used extensively with machines that may be moved frequently. Most of the combination units are designed to recirculate the cleaned air in the working space, a fact which will often determine the type of dust collector required or the advisability of using this type of unit.

There are many different designs of unit dust collectors incorporating various types of dust collectors. Most designs are manufactured in a range of standard sizes. The smaller units, designed for use with grinding wheels or small individual machines, often consist of a fan which either draws or blows the air through some type of filter. Either dry or viscous filters may be used. In some units of this design the coarser heavy particles are removed ahead of the filter by a settling chamber, baffle type, or centrifugal type collector. This feature is very desirable unless the dust concentration is quite low. The dynamic fan type of dust collector, such as is illustrated in Fig. 5, is often built into a combination unit with filters on the fan outlet. The filter area should be adequate for the design air volume and suitable for the sort of dust to be handled. Also, the fan should be capable of maintaining the rated capacity throughout normal operation without too frequent cleaning or replacement of the filters.

Wet scrubber-type collectors, such as the one shown in Fig. 8, are commonly assembled in combination units. They are especially adaptable when the dust is of an inflammable or explosive nature. In most of these units a settling tank is built into the common casing and the water is recirculated so that no drain connection is needed. Provision must be made, however, for addition of make-up water. When the dust is of the nuisance type, its removal in the form of a sludge also eliminates the possibility of contamination of the air when the dust is being removed from the unit.

Electric precipitators of the low-voltage, double-stage type are frequently combined with a fan into a unit suitable for low concentrations of fine dusts, fumes, or oil mists. Since with this type of unit it is important that the dust does not build up on the plates, a regular and frequent cleaning schedule should be established.

PNEUMATIC CONVEYING. Systems for conveying bulk materials in air can be divided into two types: (1) low-pressure systems, in which the air-to-material ratio is high and the velocities are fairly low so that the pressure loss in the system is low, and (2) high-pressure systems, which use a lower air-to-material ratio requiring higher velocities and thus have higher pressure losses. The limiting pressure for the low-pressure system is generally the maximum pressure that can economically be obtained with a centrifugal fan. High-pressure systems are thus those that require a vacuum pump, positive pressure blower, or steam jet to produce the necessary pressure. This discussion will be limited to the low-pressure type of system since the high-pressure types are discussed elsewhere in this book. (See p. 26-43.)

The nature of the material to be conveyed is generally the most important factor to consider in pneumatic conveying. Free-flowing granular materials can be very easily conveyed in air, but this method of conveying is not satisfactory for materials which tend to cake or pack. Fragile materials should not be handled in this system if reduction of the particle size is undesirable. Materials containing hazardous dust can be conveyed safely, and many materials can be transported with less contamination pneumatically than by mechanical conveyors. With proper dust-collecting equipment, the loss of material can be kept at a minimum when the quantity of material to be handled is not large. The advantages of pneumatic conveying include cleanliness, flexibility, and safety. Such systems are not so compact as mechanical conveying systems because of the space needed for the dust-separation equipment, and they have the added disadvantage of requiring more power for operation. Although the low-pressure systems require less power than the high-pressure systems, the initial cost is generally higher because of the larger air volumes handled.

Conveying Velocities. Theoretically the critical velocity for conveying a particle in air is its terminal velocity. Figures 1 and 2 illustrate the terminal velocities for fine dusts within the Stokes' law range. Although this law can be used for the fine dusts handled in exhaust systems, many of the materials handled in conveying systems consist mainly of particles larger than those for which this law applies. Stokes' law defines the terminal velocity of particles between 1 and 100 microns. The limits vary, however, depending on the density and shape of the particle. The fall of particles larger than these follows Newton's law, from which the terminal velocity can be expressed in this way:

$$V_m = K\sqrt{\frac{\rho - \rho_0}{\rho_0}d} \tag{4}$$

where K is a constant, d = diameter of the particle, ρ = density of the particle, and ρ_0 = density of the conveying fluid.

In air ρ_0 is so small compared to ρ that it can be neglected in the numerator of the fraction, and the equation shows that the velocity for a given-sized particle is directly proportional to the square root of density of the material, and inversely proportional to the square root of density of the air.

In conveying the particles must be accelerated, instead of just balanced, and the velocity must also be great enough to overcome the friction between the particle and pipe and the other particles. For these reasons, and because the velocity in the pipe is not uniform, the conveying velocity must be several times the terminal or critical velocity of the largest particle.

Pneumatic conveyor systems are similar in principle to exhaust systems, except that in the conveying systems the material concentration is considerably greater. Table 7 gives the air velocities needed to convey various types of material. The lower velocity would be satisfactory in an exhaust system; the upper velocity is required at the concentrations used in a low-pressure conveying system. These values are for standard air with a density of 0.075 lb per cu ft and, as shown by eq. 4, should be corrected for air of different density.

Carrying Capacity. The velocities given in Table 7 can be used when 50 cu ft, or 3.75 lb of standard air at 70° F. are used per pound of material to be conveyed. The weight of material that can be transported per pound of air varies directly as the square of the air velocity. Therefore, the carrying capacity of a given size of pipe increases directly as the cube of the velocity.

Since the fan horsepower required to move the air also varies as the cube of the velocity, the horsepower is proportional to the weight of material moved through a given pipe. However, since the frictional resistance of the pipe for a given velocity increases as the size of the pipe decreases, it requires more power to use high velocities and small pipes. Also smaller pipes tend to clog more easily. A pipe 10 in. in diameter is usually considered about the smallest that should be used for a pneumatic conveying system of this sort.

The same recommendations given for the central exhaust system regarding pipe smoothness, elbow design, etc., should be followed in the design of a pneumatic conveying system. The conveying pipes should, however, be made of considerably heavier gage metal because of the higher pressures and higher material concentrations. Because abrasion increases very rapidly with increases in velocity, very abrasive materials are usually handled at higher air ratios and lower velocities.

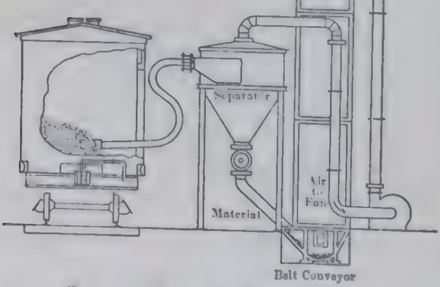

Fig. 14. Grain unloading system.

Material Feeders. In most suction systems, such as the grain-unloading system shown in Fig. 14, the material is drawn into the system through a nozzle. In this type the fan is usually placed on the clean air side of the dust separator. In some pressure systems the material is fed to the system at the fan inlet and then blown through the conveying system under pressure.

Material subject to damage by the fan impeller, or of a type harmful to the fan, may be fed into the pipe beyond the fan with a feeder like the one shown in Fig. 15. It is sometimes advantageous to use a closed system and return the air and dust not caught by the separator to the inlet side of the fan. When this is done, it is necessary to provide a small vent, which should be located as near the null point in the system as possible in order to minimize the dust loss.

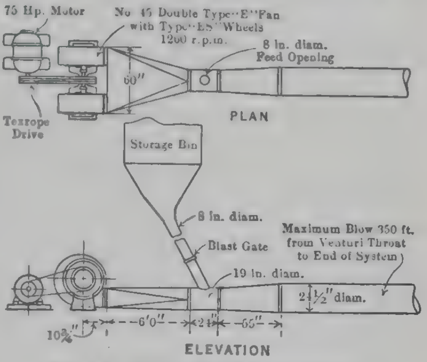

Fig. 15. Material fed beyond fan.

Material Separators. The type of separator or dust collector used to separate the material from the air stream will depend on the quantity being handled and the nature and value of the dust. When a large quantity of fairly coarse material is handled it is often blown into a large separating tank or settling chamber. Sometimes a centrifugal or cloth filter collector is used on the exhaust of the tank to catch the fine dust which does not settle out.

If the material is somewhat finer the centrifugal-cyclone type of units are used either alone or as the primary cleaner. If the value of the material is high, the high-velocity type should be used to obtain the maximum efficiency. In most pneumatic conveyor systems the concentrations are too high for the use of a cloth filter without some sort of primary cleaner ahead of it.

PRODUCT AND BY-PRODUCT RECOVERY SYSTEMS. In many industrial processes dust is formed that is valuable either as a part of the product or a by-product, and the dust-collector system is an important part of the process equipment. The collection efficiency required is usually governed by the value of the product.

Grinders, crushers, and pulverizers are typical of the type of process equipment that produces dust of this nature. In some equipment of this type all the resulting product is carried in the air stream, and the system becomes a pneumatic conveying system. More often, however, vents are provided to handle only the fine dust which is produced. The fine dust may be either mixed with the product or utilized as a by-product. The air is usually at normal room temperature, and, when the material is to be handled dry, cloth filters or centrifugal collectors are generally used. If the process is such that the material can be used wet, washer or scrubbers are often used.

Kilns. In the processing of many organic materials the product is formed by burning the raw material in a vertical or rotary kiln. The fine dust carried with the exhaust gases usually has a value either as a part of the product or as a by-product. In some cases, however, the value of the dust would not justify the cost of the recovery system and equipment required to handle the collected material. When this is true, the collection efficiency required is that necessary to eliminate a nuisance from the discharge of gases. The gases are usually handled at a high temperature and thus centrifugal collectors are most commonly used. When the temperatures are above 1000 F special stainless steel alloys are usually used in the collector construction. Single-stage electrostatic precipitators are often used when the maximum recovery is desired.

Rotary Dryers. The dusts carried by the drying gases in rotary dryers are often a valuable part of the product. Centrifugal dust collectors are generally used because of the temperature of the gases. When maximum recovery is desired cloth filters are sometimes used by bleeding in enough air to cool the gases to a safe temperature for the cloth. This latter method is limited, however, by the type of material and the amount of moisture in gases, since some dusts will cake on the cloth, and the cooling required may lower the temperature of the gases below their dew point.

Spray dryers are generally of two types. In one type a vertical drying tower is used and the velocity of the drying gases is low enough so that the majority of the dried particles fall to the bottom of the tower. This type is commonly used when the fine particles are not desired in the finished product, and the dust carried up with the gases is collected and returned to the raw material or spray liquid. Wet-type collectors are sometimes adaptable for the recovery of the dust since it can often be reused in the wet condition. Centrifugal collectors are also frequently used.

In the second type of spray drying system the gas velocity is high enough so that most of the dried material is carried with the drying gases and the material collected by the recovery system is the actual product. In this type of system the material must be collected dry, and, since a high collection efficiency is usually required, high-velocity centrifugal collectors are generally used. When the dried material is a food or drug product, the collectors can be built of the special metals required to prevent contamination of the product. Cloth filter units however, will give maximum recovery when the nature of the material and the temperature and dew point of the gases permit their use.

Coolers. When air is used as the direct cooling medium for cooling bulk materials, the finer particles are carried through the cooler with the air. Centrifugal or cloth collectors are usually used in this type of dust-collecting system.

Dusting. In some processes a powdered coating must be applied to the surface of the product. A current of air is usually used to remove the surplus powder. Dusting of rubber products and the application of bronze powder in lithographing are examples of such processes. Since the powder is usually quite valuable, cloth filters or high-efficiency centrifugal-type collectors are generally used.

Roasters, such as are used in the roasting and treatment of mineral ores, produce dust-laden gases which must be handled in a dust-collector system. The dust is sometimes of value as a by-product, and when this is the case its value will determine the collection efficiency desired. Centrifugal-type collectors or single-stage electrostatic precipitators are most commonly used because of the high gas temperature. When maximum efficiency is required a combination of both types is sometimes used.

Cleaning of ores or other powdered materials is another process in which the dust sometimes has a by-product value. In the cleaning of castings, core and molding sands are separated from the cleaning air for reuse. Almost any of the various types of dust collectors can generally be used in such systems, and the collection efficiency required will determine the type selected.

Bagging. In the bagging or packaging of powdered materials the dust produced is usually removed by ventilation air, collected and returned to the product. Cloth filters are ordinarily used unless the material is of such a nature that it plugs the cloth.

FACTORS INFLUENCING THE CHOICE OF THE TYPE OF DUST COLLECTOR. These factors will influence the type of dust collector selected for the system: (1) nature of the dust; (2) value of the dust; (3) dust concentration; (4) method of handling the collected dust; (5) collection efficiency required; (6) relative capital, operating, and maintenance costs.

MAINTENANCE AND OPERATION OF DUST-COLLECTOR SYSTEMS. Even the best designed dust-collector system can become a liability rather than an asset if not properly operated or maintained. Regular operating and inspection schedules should be set up and maintained. The entire system must be kept free of air leaks and accumulated material. Lack of attention to these requirements may not only reduce efficiency but also decrease the capacity of the system to the point where it is practically ineffective in the performance of its required functions.

Dust Handling. When receptacles or storage bins are used they should be emptied at scheduled intervals frequent enough to prevent their being filled. The method of emptying should be such that the dust is not redispersed in the air. When the dust is handled by a continuous discharge system the dust seals or valves should be maintained so that they are free of leaks.

Filters. Filter-type collectors should be cleaned or replaced before their resistance to air flow increases to the point where the capacity of the system is reduced below its rated design. Manometers should be installed to indicate when this point has been reached.

Washers. In washer-type collectors, the sprays and water piping should be kept clean to prevent plugging. Pumps should be properly lubricated and packed, and the sludge tanks should be cleaned at regular intervals.

Electrostatic precipitators should be cleaned at frequent intervals to prevent arcing and redistribution of the dust in the air or gas stream. The transformers and rectifying equipment should be maintained to operate at the design voltage.

Pipes and Fans. The pipes and air ducts should be regularly cleaned and inspected for leaks. Fans and rotating equipment must be adequately lubricated and maintained so that they are in proper balance. When there is a possibility of liquids collecting in the fan, a drain should be provided at the lowest point in the fan casing.

RECIRCULATION OF AIR FROM DUST-COLLECTOR SYSTEMS. When very large quantities of air are exhausted from a room or building, an equal amount of air must be supplied either by infiltration or by some positive source of supply such as a supply fan. In fact, some exhaust systems fail to operate properly because adequate provision has not been made to supply the quantity of air that should be exhausted. During the heating season this supply air must be heated, and, when large exhaust systems are used, the additional heating load becomes a major item in the heating cost. When air conditioning is used, the cost of conditioning all the make-up air may be quite excessive. It is apparent that serious consideration must sometimes be given to recirculation of all or part of the air after it has been thoroughly cleaned. When the portable combination units are used, all the air is generally recirculated.

Some state laws and codes have prohibited recirculation under most conditions, but the present trend is to allow it under conditions approved by the enforcement agency. The Michigan Bureau of Industrial Health does not approve installations with provision for recirculating any of the exhaust air if the contaminant is a material which may possibly impair health, regardless of the type of dust collector used. The bureau cites these reasons for disapproval: *

A. Many types of air cleaners do not collect toxic contaminants efficiently enough to remove the health hazard.

B. Poor maintenance of the air cleaner would result in the deliberate return of highly contaminated air to the breathing zone of the workers. Not being production equipment, air cleaners are too often poorly maintained.

C. Non-operation of the cleaner, through mechanical failure or through ignorance or neglect on the part of the operators, would also result in the return of highly contaminated air.

The Michigan bureau allows the recirculation of air from systems handling nuisance dust under certain conditions. In general a maximum of 10 million particles per cubic foot, on a dust count basis, is allowed in the recirculated air if certain other provisions are met. The exhaust system should be so arranged that at least 30 cu ft per min per worker is exhausted from the building. Except for portable unit-type dust collectors, the system should be constructed to provide no recirculation in the summer months if air conditioning is not used, and to prevent recirculation in case of a shutdown or failure of the air-cleaning system.

Some codes allow a recirculation of 80% of the exhaust air provided it is properly cleaned. Others allow recirculation of air equal to a certain percentage of the room or building volume.

The Division of Industrial Hygiene and Safety Standards, of the New York State Department of Labor, has tested quite a number of different types of unit dust collectors and has found that many of them do not meet their standards regarding recirculation of air from systems handling nontoxic dusts. They have set up a suggested set of standards for this type of unit: †

1. Maximum permissible recirculation for units having effluent dust count no higher than ambient without recirculation may be 1 cfm for every 10 cu ft of room volume.
2. Maximum permissible test dust count above which no recirculation would be permitted should be 3 mppcf in excess of ambient without recirculation when the unit is tested at a dust loading of 1.5 grains per cu ft of a dust having a mean size of 3 microns on a particle count basis.
3. Maximum permissible recirculation for units having effluent dust count of 3 mppcf in excess of ambient air without recirculation under above test conditions should be 1 cfm for every 100 cu ft of room volume.
4. In the intermediate range an additional 10 cu ft per cfm could be allowed for each step of 1/3 mppcf above ambient without recirculation between 0 and 3 mppcf.

The exhaust from inertial or centrifugal-type collectors, even though the efficiency is very high by weight, should never be recirculated since these dust collectors do not catch the ultrafine particles that are most injurious to the lungs. Generally, when any air is recirculated, frequent dust count surveys should be made to insure that the system is operating satisfactorily and that other conditions have not added to the dust count in the breathing zone.

COMMON LOGARITHMS

Logarithms (abbreviation *log*).—The log of a number is the exponent of the power to which it is necessary to raise a fixed number to produce the given number. The fixed number is called the *base*. Thus if the base is 10, the log of 1000 is 3, for $10^3 = 1000$. There are two systems of logs in general use, the *common*, in which the base is 10, and the Napierian, or *hyperbolic*, in which the base is 2.718281828. . . . The Napierian base is commonly denoted by e, as in the equation $e^y = x$, in which y is the Napierian log of x. The abbreviation $\log_e$ is commonly used to denote the Napierian log.

In any system of logs, the log of 1 is 0; the log of the base, taken in that system, is 1. In any system the base of which is greater than 1, the logs of all numbers greater than 1 are positive and the logs of all numbers less than 1 are negative.

The modulus of any system is equal to the reciprocal of the Napierian log of the base of that system. The modulus of the Napierian system is 1, that of the common system is 0.4342945. The log of a number in any system equals the modulus of that system × Napierian log of the number. The *hyperbolic* or *Napierian* log of any number equals the common log × 2.3025851.

Every log consists of two parts, an integral part called the *characteristic*, or index, and the decimal part, or *mantissa*. The mantissa only is given in the usual tables of common logs, with the decimal point omitted. The characteristic is one less than the number of figures to the left of the decimal point in the number whose log is to be found. The characteristic of numbers from 1 to 9.99+ is 0, from 10 to 99.99+ is 1, from 100 to 999+ is 2, from 0.1 to 0.99+ is −1, from 0.01 to 0.099+ is −2, etc. Thus,

log of	2000	is 3.30103;	log of	0.2	is −1.30103,	or	9.30103 − 10
" "	200	" 2.30103;	" "	0.02	" −2.30103,	"	8.30103 − 10
" "	20	" 1.30103;	" "	0.002	" −3.30103,	"	7.30103 − 10
" "	2	" 0.30103;	" "	0.0002	" −4.30103,	"	6.30103 − 10

The minus sign is frequently written above the characteristic thus: log 0.002 = $\bar{3}$.30103. The characteristic only is negative, the decimal part, or mantissa, being always positive.

When a log consists of a negative index and a positive mantissa, it is usual to write the negative sign over the index, or to add 10 to the index, and indicate the subtraction of 10 from the resulting logarithm. Thus log 0.2 = $\bar{1}$.30103, may be written 9.30103 − 10. The difference between a logarithm and 10 is its *arithmetical complement* or **cologarithm**.

In tables of logarithmic sines, etc., the −10 is generally omitted, as being understood.

RULES FOR USE OF THE TABLE OF COMMON LOGARITHMS.—To Find the Log of a Decimal Fraction or of a Whole Number and a Decimal.—First find the log of the quantity as if there were no decimal point, then prefix the index according to rule; **the index is one less than the number of figures to the left of the decimal point.**

Example. log of 3.14159. log of 3.141 = 0.497068. Diff. = 138.
From proportional parts 5 = 690
" " " 09 = 1242
log 3.14159 0.4971494

If the number is a decimal less than unity, the index is negative and is one more than the number of zeros to the right of the decimal point. Log of 0.0682 = $\bar{2}$.833784 = 8.833784 − 10

To Find the Number Corresponding to a Given Log.—Find in the table the log nearest to the decimal part of the given log and take the first four digits of the required number from the column N and the top of the column containing the log which is the next less than the given log. To find the 5th and 6th digits subtract the log in the table from the given log, and multiply the difference by 100, and divide by the figure in the Diff. column opposite the log; annex the quotient to the four digits already found, and place the decimal point according to the rule; the number of figures to the left of the decimal point is one greater than the index. The number corresponding to a log is called the anti-logarithm.

Find the anti-log of.............................. 0.497150
Next lowest log in table corresponds to 3141........ 0.497068 Diff. = 82.
Tabular diff. = 138; 82 ÷ 138 = 0.59+

The index being 0, the number is therefore 3.14159+.

Multiplication by Means of Logarithms.—Add together the logs of the two numbers to be multiplied. The sum is the log of the product.

a. Where both factors are greater than unity.

Example. $31 \times 1274 = 39{,}494$.

Solution. $\log 31 + \log 1274 = 1.491362 + 3.105169 = 4.596531 = \log 39{,}494$.

b. Where one or more factors are less than unity, the logs with a negative characteristic can be handled most conveniently by adding and subtracting 10.

Example. $.000028961 \times .084507 = .0000024474$.

Solution. $\log .000028961 + \log .084507 = \bar{5}.461814 + \bar{2}.926893$.

$$= (5.461814 - 10) + (8.926893 - 10) = 14.388707 - 20 = \bar{6}.388707$$
$$= \log .0000024474.$$

Division by Means of Logarithms.—Subtract the log of the divisor from the log of the dividend. The remainder is the log of the quotient.

a. When the divisor is smaller than the dividend.

Example. $2987 \div 63 = 47.41284$.

Solution. $\log 2987 - \log 63 = 3.475235 - 1.799341 = 1.675894 = \log 47.41284$.

b. When the divisor is larger than the dividend, add and subtract as many tens as may be necessary to the log of the dividend and proceed as before.

Example. $.000672 \div 263 = .00000255513$.

Solution. $\log .000672 - \log 263 = \bar{4}.827369 - 2.419956$
$$= 6.827369 - 2.419956 - 10 = \bar{6}.407413 = \log .00000255513.$$

c. The log of a fraction is obtained by subtracting the log of the denominator from the log of the numerator. Thus,

$$\log \frac{a}{b} = \log a - \log b.$$

To Raise a Number to Any Given Power.—Multiply the log of the number by the exponent of the number, and find the number whose log is the product.

a. Where the exponent consists of one figure.

Example. $16.2^3 = 4251.528$.

Solution. $3 \times \log 16.2 = 3 \times 1.209515 = 3.628545 = \log 4251.528$.

b. Where the exponent consists of two or more figures, it is best to multiply the characteristic and mantissa separately.

Example. $.005624^{.37} = .147067$.

Solution. $.37 \times \log .005624 = .37 \times \bar{3}.750045 = .37 \times (-3) + .37 \times .750045$
$$= -1.11 + .277517 = \bar{1}.167517 = \log .147067.$$

c. Where the number is a fraction, first find the log of the fraction and then multiply it by the exponent.

Example. $\left(\frac{276}{.032}\right)^{.72} = 681.9396$.

Solution. $.72\,(\log 276 - \log .032) = .72\{2.440909 - (8.505150 - 10)\}$
$$= .72 \times 3.935759 = 2.833746 = \log 681.9396.$$

To Extract Any Root of a Number.—Divide the log of the number by the index of the root, and find the number whose log is the quotient.

To extract the root of a decimal: *a.* When the root index is positive and evenly divisible into the negative characteristic of the log of the number, the division may be performed with the negative characteristic written in its usual place.

Example. $\sqrt[4]{.0006954} = .16239$.

Solution. $\log .0006954 \div 4 = \bar{4}.842235 \div 4 = \bar{1}.210559 = \log .16239$.

b. When the root index is positive and not even divisible into the negative characteristic, add to the log of the number, and indicate the subtraction from it, the smallest integral multiple of the root which will eliminate the negative characteristic. Divide the result by the root index and ascertain the number whose log corresponds to the quotient.

Example. $\sqrt[3.1]{.00002785} = .03393$.

Solution. $\log .00002785 = \bar{5}.444825$; $\bar{5}.444825 \div 3.1 = \{(2 \times 3.1) + \bar{5}.444825 - 2 \times 3.1\} \div 3.1$
$$= \{1.644825 - 6.2\} \div 3.1 = 2.530589 = \log .03393.$$

c. When the root index is negative, determine the excess of the negative characteristic over the positive mantissa. Divide the result by the root index and ascertain the number whose log corresponds to the quotient.

Example. $\sqrt[-4]{.000003976} = 22.394$.

Solution. $\log .000003976 = \bar{6}.599446 = .599446 - 6 = -5.400554$;
$$-5.400554 \div (-4) = 1.350138 = \log 22.394.$$

Solution of Exponential Equations.—In an exponential equation, the unknown quantity is the exponent, thus $a^x = b$. This may be transformed to $\log a^x = \log b$, or $x \log a = \log b$, whence $x = \log b \div \log a$.

a When the base is greater than unity, put the equation in the form $x = \log b \div \log a$. Then $\log x = \log (\log b) - \log (\log a)$.

Example. $32.6^x = 14.632$.

Solution. $\log x = \log (\log 14.632) - \log (\log 32.6) = \log 1.165303 - \log 1.513218$
$= .066439 - .179901 = \bar{1}.886538;\ x = .77008$.

b When both the known quantities are decimal, put the equation in the form $x = \log b \div \log a$. Subtract the positive mantissa from the negative characteristic in both divisor and dividend, obtaining negative remainders. Change the signs of divisor and dividend and proceed as in Case *a*.

Example. $.0729^x = .2693$.

Solution. $x = \log .2693 \div \log .0729 = \bar{1}.430236 \div \bar{2}.862728$
$= (-.569764) \div (-1.137272) = .569764 \div 1.137272;$
$\log x = \log .569764 - \log 1.137272 = \bar{1}.755695 - .055864 = \bar{1}.699831$
$x = .50099$.

c When only one of the known quantities is a decimal, put the equation in the form $x = \dfrac{\log b}{\log a}$. Subtract the positive mantissa from the negative characteristic of the numerator or denominator as the case may be, and rewrite the fraction with the remainder so obtained as the new numerator or denominator. Make both numerator and denominator positive, but write a minus sign in front of the fraction, to signify that the result will be a negative quantity. Solve the fraction by logarithms and write a minus sign in front of the result.

Example. $.726^x = 802.7$.

Solution. $x = \dfrac{\log 802.7}{\log .726} = \dfrac{2.904553}{\bar{1}.860937} = \dfrac{2.904553}{-.139063} = -\dfrac{2.904553}{.139063}$.

$\log x = -(\log 2.904553 - \log .139063) = -(.463079 - \bar{1}.143211) = -(1.319868)$
$x = -20.8867$

d When the exponent is negative and one of the known quantities is less than unity, put the equation in the form $(-x) = \dfrac{\log b}{\log a}$. Subtract the positive mantissa from the negative characteristic, as in Case *c*, and multiply both sides of the resulting equation by (-1). Find the value of x as in Case *c*.

Example. $10.78^{-x} = .09431$.

Solution. $x = \dfrac{\log .09431}{\log 10.78} = \dfrac{\bar{2}.974558}{1.032619};\ x = \dfrac{1.025442}{1.032619}$.

$\log x = .010911 - .013940 = \bar{1}.996971.\quad x = .99305$.

Table 1. Logarithms of Numbers from 1 to 100

Table 3. Natural (Napierian or Hyperbolic) Logarithms of Numbers

Table gives natural logarithms of numbers from 1.0 to 9.99 directly. To find logarithms of numbers outside that range add or subtract natural logarithm of the powers of 10 as follows:

$\log_e 10 = 2.302585$ $\log_e 10^4 = 9.210340$ $\log_e 10^7 = 16.118096$
$\log_e 10^2 = 4.605170$ $\log_e 10^5 = 11.512925$ $\log_e 10^8 = 18.420681$
$\log_e 10^3 = 6.907755$ $\log_e 10^6 = 13.815511$ $\log_e 10^9 = 20.703266$

Example.—$\log_e 679. = \log_e 6.79 + \log_e 10^2 = 1.9155 + 4.6052 = 6.5207$
$\log_e .0679 = \log_e 6.79 - \log_e 10^2 = 1.9155 - 4.6052 = -2.6897$

The base of natural logarithms is $e = 2.7182818$. Therefore $\log_e N = \log_e 10 \times \log_{10} N = 2.302585 \log_{10} N$; and $\log_{10} N = \log_{10} e \times \log_e N = 0.434294 \log_e N$.

Table 4 on the preceding page gives values of e^x, e^{-x}, sinh x, cosh x, and tanh x for values of x from 0.00 to 6.00 in intervals of 0.10.

To facilitate computations involving multiplication, the common logarithms of e^x, sinh x, cosh x, and tanh x are also given.

For values of x greater than 6: e^x may be computed from the relationship $e^x = \log^{-1}(x \log_{10} e) = \log^{-1} 0.43429x$; e^{-x} approaches zero; sinh x and cosh x are approximately equal and become 0.5 e^x; and tanh x and coth x have values approximately equal to unity.

Where more accurate values of the exponentials and functions are required they may be computed from the following relationships.

$$e = 2.71828\ 18285 \qquad \frac{1}{e} = 0.36787\ 94412$$

$$M = \log_{10} e = 0.43429\ 44819 \qquad \frac{1}{M} = \log_e 10 = 2.30258\ 50930$$

$$e^x = \log^{-1} Mx \qquad e^{-x} = \log^{-1} - Mx$$

$$\sinh x = \frac{e^x - e^{-x}}{2} \qquad \cosh x = \frac{e^x + e^{-x}}{2} \qquad \tanh x = \frac{e^x - e^{-x}}{e^x + e^{-x}}$$

$$\operatorname{csch} x = \frac{1}{\sinh x} \qquad \operatorname{sech} x = \frac{1}{\cosh x} \qquad \coth x = \frac{1}{\tanh x}$$

Table 5. Certain Constants Containing e and π

$e = 2.7182818285$ $\qquad M = \log_{10} e = 0.4342944819$

$\pi = 3.1415926536$ $\qquad M^{-1} = \log_e 10 = 2.3025850930$

CIRCULAR ARCS, CHORDS, SEGMENTS AND SECTORS

Notation.—A = central angle, degrees; C = chord of arc; c = chord of $1/2$ arc; D = diameter; G = area of segment; H = rise of arc or height of segment; L = length of arc; R = radius; S = area of sector.

L (exact) $= 2\pi RN/360 = 0.017453RN$

L (approx.) $= (8c - C)/3 = [(2c \times 10H)/(60D - 27A)] + 2c$

$= [(\sqrt{C^2 + 4H^2} \times 10H^2)/(15C^2 + 33H^2)] + 2c$

$C = 2\sqrt{c^2 - H^2} = \sqrt{D^2 - (D - 2H)^2} = 8c - 3L = 2\sqrt{R^2 - (R - H)^2} = 2\sqrt{(D - H) \times H}$

$C/2 = \sqrt{H \times (D - H)}$; $c = 1/2\sqrt{C^2 - 4H^2} = \sqrt{D \times H} = (3L + C)/8$

$D = c^2/H = (1/4\,C^2 + H^2)/H$

$H = c^2/D = 1/2[D - \sqrt{D^2 - C^2}]$ when $H < R$; $= 1/2[D + \sqrt{D^2 - C^2}] = \sqrt{c^2 - 1/4\,C^2}$ when $H > R$

$G = S - 1/2\,C\sqrt{R^2 - 1/4\,C^2}$ when $G <$ semi-circle; $= S + 1/2\,C\sqrt{R^2 - 1/4\,C^2}$ when $S >$ semi-circle

$= S - (C/2)(R - H) = 1/2\,[(L - C)(D/2) + CH]$

$S = 1/2\,LR = \pi AR^2/360 = (\pi R^2/360) \times 2[\sin^{-1}\{(C/2)/R\}]$; $R = (C^2+4H^2)/8H$

* Area of segment of any radius = factor G × square of radius

Table 9. Areas of Segments of a Circle

Area = $F \times D^2$ where segment < semicircle; = $\frac{1}{4}\pi D^2$ − (area of segment of rise h). H = rise or height of segment, D = diam. of circle; F = factor corresponding to H/D. $h = (D - H)$

* For circumferences and areas of circles, diameters in inches, see Table 7, pp. 28-26 to 28-42.

The following tables give the values of sin x, cos x, and tan x for values of x from 0 to 90° in intervals of 0.1 degree. By making use of the periodic character of these functions, the values can be determined from these tables for all values of x to an accuracy of 0.1 degree. The following relations facilitate this determination for any quadrant:

$$\sin x = +\sin(180^\circ - x) = -\sin(180^\circ + x) = -\sin(360^\circ - x)$$

$$\cos x = -\cos(180^\circ - x) = -\cos(180^\circ + x) = +\cos(360^\circ - x)$$

$$\tan x = -\tan(180^\circ - x) = +\tan(180^\circ + x) = -\tan(360^\circ - x)$$

$$\text{Angle in degrees} = \text{angle in radians} \times 180/\pi$$

3900	7052	7070	7088	7106	7124	7142	7160	7178	7196	7214

Following is a comparison of temperature scales at significant points:

Temperature Scale	For Water at Sea Level		Absolute Zero
	Boiling Pt.	Freezing Pt.	
Fahrenheit	212	32	−459.69
Centigrade	100	0	−273.16
Rankine (Fahrenheit Absolute)	572	492	0
Kelvin (Centigrade Absolute)	283	273	0
Réaumur	80	0	−218.53

To convert from one scale to another, use the following formulas:

Temperature Fahrenheit = $^{9}/_{5}$ × temp. C + 32° = $^{9}/_{4}$ temp. R + 32°
Temperature Centigrade = $^{5}/_{9}$ (temp. F − 32°) = $^{5}/_{4}$ temp. R
Temperature Réaumur = $^{4}/_{5}$ temp. C = $^{4}/_{9}$ (temp. F − 32°)

MEASURES AND WEIGHTS COMMONLY USED IN THE UNITED STATES AND GREAT BRITAIN

Abbreviations

bbl.	= barrel	dwt.	= pennyweight	hr.	= hour	quin.	= quintal
bu.	= bushel	fath.	= fathom	Imp.	= Imperial (bu., gal.)	qr.	= quarter
chn.	= chain	ft.	= foot	in.	= inch	qt.	= quart
circm.	= circumference	fl. drm.	= fluid drachm	lea	= league	scr.	= scruple
cir. in.	= circular inch	fl. oz.	= fluid ounce	m. pace	= military pace	sec.	= second
cir. mil.	= circular mil	furl.	= furlong	min.	= minute	sq.	= square (in., ft., etc.)
cwt.	= hundred weight	gal.	= gallon (U.S.)	naut. mi.	= nautical mile	stat. mi.	= statute mile
deg.	= degree	grn.	= grain	pnch	= puncheon	trce.	= tierce
drm.	= drachm (dram)	hghd.	= hogshead	quad.	= quadrant	yd.	= yard

Table 19. Measures of Length

Long Measure

12 in. = 1 ft.
3 ft. = 1 yd.
5 1/2 yd. = 16 1/2 ft. = 1 rod, pole or perch
40 poles = 220 yd. = 1 furl.
8 furl. = 1760 yd. = 5280 ft. = 1 mile
4 in. = 1 hand
9 in. = 1 span
2 1/2 ft. = 1 m. pace.

Land, Surveyors, or Gunter's Measure

7.92 in. = 1 link
100 links = 66 ft. = 4 rods = 1 chn.
10 chn. = 220 yd. = 1 furl.
8 furl. = 80 chn. = 1 mile.

Nautical Measure

6080.26 ft. = 1.15156 stat. mi. = 1 naut. mi.
3 naut. mi. = 1 lea.
60 naut. mi. = 1 deg. (at equator)
6 ft. = 1 fath.
120 fath. = 1 cable
1 naut. mi. per hr. = 1 knot.

Table 20. Measures of Area

Square Measure

144 sq. in. = 183.35 cir. in. = 1 sq. ft.
9 sq. ft. = 1 sq. yd.
30 1/4 sq. yd. = 272 1/4 sq. ft. = 1 sq. rod

$$\left.\begin{array}{l}160 \text{ sq. rods} = 10 \text{ chn.}\\ 4840 \text{ sq. yd.} = 43560 \text{ sq. ft.}\end{array}\right\} = 1 \text{ acre}$$

640 acres = 27,878,400 sq. ft. = 1 sq. mile
1 acre = $(208.71 \text{ ft.})^2$

$$1 \text{ cir. in.} = \left\{\begin{array}{l}\text{area of circle 1 in. diam.}\\ \quad = 0.7854 \text{ sq. in.}\end{array}\right.$$

$$1 \text{ cir. mil} = \left\{\begin{array}{l}\text{area of circle 0.001 in. diam.}\\ \quad = 0.0_57854 \text{ sq. in.}\end{array}\right.$$

1,000,000 cir. mil = 1 cir. in.

Board Measure

144 cu. in. = 12 × 12 × 1 in. = 1 board ft.

The above definition of a board foot applies to rough green lumber. American practice uses a yard standard of 29/32 in. thick and an industrial standard of 7/8 in. thick for rough dry lumber; for dressed lumber the corresponding thicknesses are 25/32 in. and 13/16 in. For example, a rough dry piece 12 × 12 × 29/32 in. contains 1 board ft. Board ft. in round timber = $(1/4\, c \times d \times l)/144$. c = mean circm., d = diam., l = length, all in ft.

Table 21. Measures of Weight

(The grain is the same in all systems.)

Avoirdupois Weight

16 drm. = 437.5 grn. = 1 oz.
16 oz. = 7000 grn. = 1 lb.
14 lb. = 1 stone
28 lb. = 2 stone = 1 qr.
100 lb. = 1 quin.
4 qr. = 112 lb. = 1 cwt.
20 cwt. = 2240 lb. = 1 long ton
2000 lb. = 1 short ton.

Troy Weight (for gold and silver)

24 grn. = 1 dwt.
20 dwt. = 480 grn. = 1 oz.
12 oz. = 5760 grn. = 1 lb.
1 Assay ton = 29,167 milligrams

$$= \left\{\begin{array}{l}\text{Troy oz. per 2000 lb.}\\ \quad \text{ton avoirdupois}\end{array}\right.$$

Carat Weight (for precious stones)

1 carat = 3.086 grn. = 0.200 gram

Apothecaries' Weight

20 grn. = 1 scr. ℈
3 scr. = 60 grn. = 1 drm. ʒ
8 drm. = 480 grn. = 1 oz. ℥
12 oz. = 5760 grn. = 1 lb.

Table 22. Measures of Volume

Cubic Measure

1728 cu. in. = 1 cu. ft.
27 cu. ft. = 1 cu. yd.

$$1 \text{ cord of wood} = \left\{\begin{array}{l}4 \times 4 \times 8 \text{ ft.}\\ \quad = 128 \text{ cu. ft.}\end{array}\right.$$

$$1 \text{ perch masonry} = \left\{\begin{array}{l}16\ 1/2 \times 1\ 1/2 \times 1 \text{ ft.}\\ = 23\ 3/4 \text{ cu. ft.}\end{array}\right.$$

Liquid Measure

4 gills = 1 pint
2 pints = 1 qt.
4 qt. = 231 cu. in. = 8.3356 lb. H_2O
= 1 U. S. gal.
= 0.8327 Imp. gal.
1 Imp. gal. = 277.420 cu. in.
= 10 lb. H_2O
1.20094 U. S. gal. = 1 Imp. gal.
7.4805 U. S. gal. = 1 cu. ft.

Old Liquid Measure

31 1/2 gal. = 1 bbl.
42 gal. = 1 trce.
2 bbl. = 63 gal. = 1 hghd.
84 gal. = 2 trce. = 1 pchn.
2 hghd. = 126 gal. = 1 pipe or butt
2 pipes = 3 pchn. = 1 tun.

Apothecaries' Fluid Measure

60 minims = 1 fl. drm.
8 drm. = 1 fl. oz.
1 fl. oz. = 1/128 U. S. gal. = 1.8047 cu. in. = 456.3 grn. H_2O at 39° F.
16 fl. oz. = 1 pint
1 fl. oz. (British) = 1.732 cu. in.
= 437.5 grn. H_2O at 62° F.

Dry Measure

2 pints = 1 qt.
8 qts. = 1 peck
4 pecks = 2150.42 cu. in.
= 1 bu. (struck)
1 1/4 bu. (struck) = 1 bu. (heaped)
105 qts. (struck) = 7056 cu. in. = 1 bbl.
8 Imp. gal. = 2218.192 cu. in.
= 1 Imp. bu.
8 Imp. bu. = 1 qr.

Shipping Measure

100 cu. ft. = 1 Register ton *
40 cu. ft. = 31.143 U. S. bu.
= 1 shipping ton (U. S.) †
42 cu. ft. = 32.719 Imp. bu.
= 1 shipping ton (British) †

* For measurement of entire internal capacity. † For measurement of cargo.

Miner's Inch

A variable unit, defined by statute in different states as the quantity of water that will flow through an orifice of 1 sq. in. area, under a head ranging from 4 1/2 to 6 in. U. S. Reclamation Service defines the miner's inch as 1 cu. in. per sec. The law governing the locality in which the measurement is to be made should be consulted.

Table 23. Circular Measure

60 sec. = 1 min.
60 min. = 1 deg.
90 deg. = 1 quad.
360 deg. = circum.
57.2957795 deg. = 1 radian
= 57° 17′ 44.806″
1 radian = angle of arc equal to radius.

Table 24. Time

60 sec. = 1 min.
60 min. = 1 hr.
24 hr. = 1 day
7 days = 1 week
52 weeks = 1 year
1 year (exact) = 365 days, 5 hr., 48 min., 45.6 sec.

A year divisible by 4 is a leap year and contains 366 days, except centesimal years, of which only those divisible by 400 are leap years.

365.24734 mean solar days = 1 yr.
= 366.008515 sidereal days
24 hr. mean solar time
= 23 hr. 56 min., 49.9 sec. sidereal time
1 mean solar day
= 1 mean sidereal day + 3 min., 10.1 sec.

THE METRIC SYSTEM

The fundamental standard of length in the metric system is the International Standard Meter, derived from the Metre des Archives, Paris. Its length is defined as the distance between two lines at 0° C. on a platinum-iridium bar deposited at the International Bureau of Weights and Measures near Paris. 1 meter = 39.37 in.

The fundamental standard of mass is the International Standard Kilogram, which is a mass of platinum-iridium, deposited at the International Bureau, whose weight *in vacuo* is the same as that of the Kilogram des Archives.

The fundamental unit of volume is the **liter**, which is defined as the volume of a kilogram of water at the temperature of maximum density, 4° C., under a pressure of 76 cm. of mercury. The liter originally was defined as a cubic decimeter, but is slightly greater. The generally accepted relation between the cubic decimeter and the liter is 1 liter = 1.000027 cu. decimeters.

The unit of force is the **dyne**, which is the force which acting for 1 second on a mass of one gram will produce a velocity of 1 centimeter per second. 1 dyne = (1/980.665) gram. 1,000,000 dynes = 1.020 kilograms force = 2.248 lb. force. 1 lb. force = 0.4536 kilogram force = 444,800 dynes.

The unit of heat is the **gram-calorie**, which is the quantity of heat required to raise 1 gram of water 1° C.

Table 25. Units of Metric Measures *

Length			Area		
Unit	Symbol	Value in Meters	Unit	Symbol	Value in Sq. Meters
Micron	μ	0.000 001			
Millimeter	mm.	0.001	Sq. millimeter	sq. mm.	0.000 001
Centimeter	cm.	0.01	Sq. centimeter	sq. cm.	0.000 1
Decimeter	dm.	0.1	Sq. decimeter	sq. dm.	0.01
Meter (unit)	m.	1.0	Sq. meter (centiare)	sq. m.	1.0
Dekameter	dkm.	10.0	Sq. dekameter (are)	sq. dkm.	100.0
Hectometer	hm.	100.0	Hectare	ha.	10,000.0

Table 34. Metric Equivalents of Power, Work, and Energy *

English to Metric	Log	Metric to English	Log
1 ft-lb = 0.138255 kg-m	$\bar{1}.140680$	1 kg-m = 7.2330 ft-lb	0.859318
= 0.0$_6$37650 kwhr	$\bar{7}.575765$	= 0.0$_5$365304 hp-hr	$\bar{6}.562655$
= 0.32379 IT cal	$\bar{1}.510263$	= 0.0$_2$92938 Btu	$\bar{3}.968193$
1 hp = 76.042 kg-m per sec	1.881053	1 kwhr = 2.656000 ft-lb	6.424228
= 0.76042 poncelet	$\bar{1}.881053$	= 1.3414 hp-hr	0.127558
= 1.01389 cheval vapeur	0.005994	= 3412.75 Btu	3.533103
1 hp-hr = 273,750 kg-m	5.437355	1 cheval vapeur = 0.9863 hp	$\bar{1}.994009$
= 0.74548 kwhr	$\bar{1}.872435$	1 poncelet = 1.3151 hp	0.118959
= 641,100 IT cal	5.806926	1 IT cal † = 3.0884 ft-lb	0.489738
1 Poncelet = 100 kg-m per sec	2.000000	= 0.0$_5$155980 hp-hr	$\bar{6}.193070$
1 cheval-vapeur = 75 kg-m per sec	1.875061	= 0.0$_2$39683 Btu	$\bar{3}.598605$
1 Btu = 251.996 IT cal	2.401400	= 1.00037 mean calories	0.000160
= 107.599 kg-m	2.031808		
= 0.0$_3$29302	$\bar{4}.466898$		

---

* A subscript after a figure indicates the number of times it is repeated. Thus 0.0$_3$8 = 0.0008.

† The IT cal is defined as $\frac{1}{860}$ of the international watthour, and is nearly equal to the mean calorie; 1 IT cal = 1.00037 mean calories, or 1 Btu = 251.996 IT cal. (See *Mechanical Engineering*, Nov. 1935, p. 710.)

SYMBOLS AND ABBREVIATIONS

Greek Letters

Α	α	Alpha	Η	η	Eta	Ν	ν	Nu	Τ	τ	Tau
Β	β	Beta	Θ	ϑ θ	Theta	Ξ	ξ	Xi	Υ	υ	Upsilon
Γ	γ	Gamma	Ι	ι	Iota	Ο	ο	Omicron	Φ	φ	Phi
Δ	δ	Delta	Κ	κ	Kappa	Π	π	Pi	Χ	χ	Chi
Ε	ε	Epsilon	Λ	λ	Lambda	Ρ	ρ	Rho	Ψ	ψ	Psi
Ζ	ζ	Zeta	Μ	μ	Mu	Σ	σ ς	Sigma	Ω	ω	Omega

Mathematical Signs and Abbreviations

$+$ plus (addition).
$+$ positive.
$-$ minus (subtraction).
$-$ negative.
$\pm$ plus or minus.
$\mp$ minus or plus.
$=$ equals.
$\geqq$ equals or greater than.
$\leqq$ equals or is less than.
$\approx$ approximately equals.
$\times$ multiplied by.
ab or $a.b = a \times b$.
$\div$ divided by.
$/$ divided by.
$\frac{a}{b} = a/b = a \div b$. $15/16 = \frac{15}{16}$.
$0.2 = \frac{2}{10}$; $0.002 = \frac{2}{1000}$.
$\sqrt{\ }$ square root.
$\sqrt[3]{\ }$ cube root.
$\sqrt[4]{\ }$ 4th root.
: is to, : : so is, : to (proportion).
2 : 4 : : 3 : 6, 2 is to 4 as 3 is to 6.
: ratio; divided by.
2 : 4, ratio of 2 to 4 = 2/4.
$>$ greater than.
$<$ less than.
° degrees, arc or thermometer.
′ minutes or feet.
″ seconds or inches.
′ ″ ‴ accents to distinguish letters, as a', a'', a'''.
a_1, a_2, a_3, a_b, a_c, read a sub 1, a sub b, etc.
( ) [ ] { } —— parentheses, brackets, braces, vinculum; denoting that the numbers enclosed are to be taken together; as, $(a + b)c = \overline{4 + 3} \times 5 = 35$.
a^2, a^3, a squared, a cubed.
a^n, a raised to the nth power.
$a^{2/3} = \sqrt[3]{a^2}$, $a^{3/2} = \sqrt{a^3}$.
$a^{-1} = \frac{1}{a}$, $a^{-2} = \frac{1}{a^2}$.
10^9 = 10 to the 9th power = 1,000,000,000.
$\sin a$ = the sine of a.
$\sin^{-1} a$ = the arc whose sine is a.
$\sin a^{-1} = \frac{1}{\sin a}$.
log = logarithm.
$\log_e$ or hyp log = hyperbolic logarithm.
% per cent.
∠ angle.
△ triangle.
sin, sine.
cos, cosine.
tan, tangent.
sec, secant.
versin, versed sine.
cot, cotangent.
cosec, cosecant.
covers, co-versed sine.

In Algebra, the first letters of the alphabet, a, b, c, d, etc., are generally used to denote known quantities, and the last letters, w, x, y, z, etc., unknown quantities.

Abbreviations and Symbols commonly used.

d, differential (in calculus).
$\int$, integral (in calculus).
$\int_b^a$, integral between limits a and b.
Δ, delta, difference.
Σ, sigma, sign of summation.
π, pi, ratio of circumference of circle to diameter = 3.14159.
g, acceleration due to gravity = 32.16 ft. per second per second.

INDEX

- **Abbreviations,** mathematical, 28-60
- **Abrasion resistance,** refractories, 5-50
  - rubber, 5-58
- **Abrasive belts,** 23-97, 23-98
- **Abrasive cut-off disks,** 23-111
- **Abrasive processes,** 23-71 to 23-101
- **Abrasive wheels,** 23-71 to 23-89 (*see also* Grinding wheels)
  - factor of safety, 23-89
  - guarding, 27-85
  - selection, 23-73 to 23-84, (table) 23-75
  - shapes, 23-84
- **Abrasives,** 23-71
  - grain size, 23-71
  - polishing, 23-97

- **Circular arc,** center of gravity, 7-19
- **Circular arcs,** chords, segments (table), 28-42, 28-43

Circular measure, 28-56
Circular mil, 6-04, 16-02
Circular pitch (def), 14-04, (table) 14-09
Circular plate, moment of inertia, 7-20
  radius of gyration, 7-21
Circular ring, moment of inertia, 7-20
Circular saws, 23-110 to 23-112
  cutting speeds, feeds, and rake angles for (table), 23-111
Circular thickness, gear teeth (def), 14-04
Circumference of circles (table), 28-26 to 28-42
  in feet (table), 28-46
Clad alloys, 4-17
Clad aluminum alloys, corrosion resistance, 3-29
Clad steel, 2-50
Clamp shaft coupling, 15-18
Clamps, center, leaf springs, 11-30
  wire rope, 6-20
Clay (def), 27-54
  grinding wheels for, 23-79
  specific gravity, 1-29
Clay sewer pipe, 5-16
Clay tile, floor system, 27-22
  structural, 5-15
  for walls, 27-46
Clearance, gear (def), 14-03
  journal bearings, 12-16 to 12-31
    accepted practice, 12-50 to 12-53
Clearance angle, milling, 23-54
Clearance fit (def), 24-07
Cleveland track, 26-28
Cleveland twist drill tapers, 18-20
Clinkers, conveying, 27-102
Clips, rebound, leaf springs, 11-30
  wire rope, 6-18
Clock brass, 4-32, 4-33
Clothflex wheels, polishing, 23-96
Cluster vertical borers, 25-44
Clutches, 15-31 to 15-39
  centrifugal, 15-32
  cone, 15-33
  disk, 15-31
  electromagnetic, 15-38
  fluid, 15-36 to 15-38
  friction, 15-31 to 15-35
  jaw, 15-36
  magnetic, 15-34
  overrunning, 15-38
  positive-engagement, 15-35
  roller, 15-38
  spring, 15-38
Coal, conveying, 26-36, 27-102
  elevators, speeds (table), 26-31
  for industrial heating, 22-07, 22-11
  specific gravity, 1-29
  storage bridges, 26-21
Coal tar, for industrial heating, 22-07
Coal-tar creosote wood preservative, 25-28
Coarse-thread series, 10-09 (*see also* Screw threads)
Coatings, bituminous, 3-15
  cadmium, 3-12
  galvanized, 3-10
    tests and specifications, 3-12, 4-60
  lead, 3-12
  organic, 3-08
  oxide, for aluminum, 4-21
  phosphate, 3-10
  Portland cement, 3-16
  zinc, 3-10 to 3-12
Cobalt, 1-03, 1-04, 4-69
  compressibility, 1-31
Cobalt steels, tool, 23-22
Codes, building, 27-02 to 27-12
Coefficient of discharge, nozzles and orifices, 13-05
Coefficient of expansion, 1-04 (*see also* Thermal expansion)
Coefficient of fluctuation, flywheels, 7-40
Coefficient of friction, 7-27 (*see also* Friction coefficient)
Coefficient of steadiness, flywheels, 7-40
Coefficient of viscosity, 12-03
Coining, 20-31
  powder metal parts, 19-47
Coke, specific gravity, 1-29
Coke oven gas, 22-07
Cold heading, 20-07
Cold molding, 25-52, 25-53
Cold reduction, effect on stress-strain curve, 20-20
Cold shuts, wire rope hoisting, 26-07
Cold-worked carbon steel, specification, 2-40
Cold working, aluminum alloys, 4-10, 4-12
  effect on fatigue, 8-42
  effect on metals, 1-13
Collars, shaft, 12-42
Collectors, dust, 27-93 to 27-99 (*see also* Dust collectors)
  electric current, for hoists, 26-27
Color, temperature, 27-64, 27-70
  wavelength, 27-70
Columbium, 1-03, 1-04, 4-69
Columns, 8-21 to 8-27, (def) 8-21
  aluminum alloy, strength (table), 4-15
  bending loads, 8-24
  eccentric loads, 8-24
  end conditions, 8-21
  footings for, 27-56
  formulas, 8-22, 8-23

Cotters, friction, 7-33
Cotton, conveying, 27-102
Cotton packing, friction, 7-32
Cotton rope drives, 15-80 to 15-82
Cottonwood, 5-75, 5-84
Cottrell system, electrical precipitation, 27-98
Counterbore bits, for wood, 25-38
Countersunk bolts, dimensions (table), 10-47
Couplings, 15-17 to 15-31
  angular flexibility, 15-21
  flange, 15-18 ✓
  flexible, 15-20 to 15-27 ✓
  floating shaft, 15-26
  guarding, 27-83
  hydraulic, 15-36 to 15-38, 15-94
  hydroelectric units, dimensions (table), 15-19
  lateral flexibility, 15-21
  longitudinal flexibility, 15-21
  overload release, 15-28
  parallel flexibility, 15-21
  rigid, 15-17 to 15-20
  rubber-bushed stud, dimensions and capacities (table), 15-23
  selection factors, 15-27
  service factors, 15-26
  slip, 15-30
Coversines, logarithms of (table), 28-52
Crab hoists, 26-26
Crabwood, 5-80
Crack propagation, 2-06
Cracking, stress-corrosion, 3-18, 3-23, 3-29, 3-30
Crane chain, 6-22, 6-23
Cranes, 26-15 to 26-22
  bracket jib, 26-15
  bridge (table), 26-17
  cable, 26-10
  crawler, 26-11
  gantry, 26-19
  grab bucket, 26-19
  ingot-stripping, 26-19
  jib, 26-15
  ladle, 26-19
  level-luffing, 26-22
  locomotive, 26-11
  motors for, 16-38, 16-53
  pillar, 26-15
  portal, 26-19
  power required to drive, 26-20
  safety standards, 26-15
  soaking-pit, 26-20
  supports for, 26-20
  traveling bridge, 26-17
  traveling wall, 26-16
  types, 26-15
  walking, 26-16
Crank and rocker mechanism, 7-02
Crank mechanism, acceleration factors (table), 7-38
  inertia factors (table), 7-38
  piston positions (table), 7-04
  tangential effort (table), 7-36
  velocity factors (table), 7-36
Crankdisks, 7-35
Crankpins, 7-34 to 7-36
  center-crank, strength, 7-36
  overhung, strength and proportions, 7-35
Crankshafts, forged, 7-35
Cranks, 7-34 to 7-36
  balanced, 7-35
  center, 7-35
  overhung, 7-34
  side, 7-34
  tangential forces, 7-37
Crawler, dragline, 26-12
Crawler cranes, 26-11
Creep (def), 8-04
  equations, 8-43
  failure, 8-42
  high-temperature-resistant alloys, 4-85
  strain, 8-42
  testing machines, 8-53
Creosote, 25-29
Critical speeds, shafts, 9-13 to 9-15, 15-07
  turbine wheels, 9-16
Crobalt, 23-50
Crosby clip, wire rope, 26-06
Cross bands, plywood, 25-19
Cross-cutting saws, 25-39
Crossed-axis helical gears, 14-14 to 14-16
Crown gear (def), 14-17
Crucible furnaces, foundry, 19-35
Crushers, by-product recovery, 27-107
Crushing strength, riveted joints, 10-63
Crystalline lattice form, metallic elements (table) 1-04
Crystalline pattern, metals, 1-06
Crystals, metal, 1-02, 1-06, 1-11
Crystle, plastic, 5-42
Crystolon, abrasive, 23-71
Cube roots (table), 28-26 to 28-42

Cubes (table), 28-26 to 28-42
Cubic measure, 28-55
Cucumber magnolia, 5-79
Cup packings, 18-11
  sizes (table), 18-12
Cupola malleable iron, 2-33
Cupronickel, 4-34, 4-35, 4-51, 4-52, 4-56
Cupronickel alloys, corrosion resistance, 3-28
Curium, 1-03
Curling, sheet metal, 20-28
Current, alternating (def), 16-02
  direct (def), 16-03
  limit control, electronic, 17-33
Current pulsation, limit, 16-07
Curvature correction, springs, 11-03
Curved beams, 8-21
  stress constant (table), 8-20
Curved plywood, 25-21 to 25-23
  adhesives for, 25-23
Curvic couplings, 15-20
Curvic tooth overload release couplings (table), 15-30
Cut-off broaching, 23-105
Cut-off disks, abrasive, 23-111
Cut-off saw, woodworking, 25-34
Cutter grinders, 23-91
Cutters, composite gear tooth (table), 23-112
  fly, 23-50
  formed milling, 23-48
  milling, 23-48 to 23-52
    diameter, 23-54
  profile milling, 23-48
  for sprocket teeth, 15-75
  wood, 25-35
Cutting, electric-arc, 23-121
  flame, 23-116 to 23-121
  gas, 23-116 (*see also* Gas cutting)
  sheet metal, 20-16
Cutting angles, wood planers (table), 25-41
Cutting coolants, for magnesium, 4-44
Cutting feeds, 23-08 to 23-18 (*see also* Feeds)
  for aluminum, 4-19
  for magnesium, 4-44
Cutting fluids, 23-18 to 23-19
  for aluminum, 4-19
  drilling, 23-68
  milling, 23-57
  recommendations, 23-19
  turning, 23-28
Cutting resistance, metals, 23-29
Cutting speeds, 23-08 to 23-18, 23-29, 23-41, 23-44, 23-52, 23-109, 23-111, (def) 23-05
  for aluminum, 4-19
  for cast iron, 23-17
  circular saws, 23-111
  drilling, 23-67, (table) 23-68
  for magnesium, 4-44
  milling cutters, 23-52
  for Monel (table), 23-14
  planers, 23-41, 23-42
  saw blades (table), 23-109
  shapers, 23-44
  for steel, 23-15, 23-16
  turning, 23-29
Cutting tools, planers, 23-40
  shapers, 23-45
Cutting wood, theory, 25-34
Cycleweld, adhesive, 21-28, 21-29
Cyclograph, 8-58
Cycloid, center of gravity, 7-19
Cycloidal curve, generation, 14-02
Cycloidal motion, 7-12
  cam layout, 7-13
Cyclone hoist, 26-23
Cyclones, high-velocity, 27-94
  low-velocity, 27-93
    proportions, 27-94
Cylinder saw, 25-34
Cylinders, hydraulic, 13-12
  moment of inertia, 7-20
  radius of gyration, 7-21
  thick, stresses, 8-31
  thin, under internal and external pressure, 8-31
Cylindrical cams, 7-15
  rollers, 7-16
Cylindrical grinding, tolerances, 24-06
Cylindrical grinding machines, 23-89
Cylindrical roller bearings, 12-67, 12-99 (*see also* Bearings, roller)
Cypress, bald, 5-75, 5-84

Damping, fluid, 9-23
  noise, 9-27
  vibration, 9-09, 9-23
Damping capacity, 8-38
  testing machine, 8-55
Damping ratio, servomechanism, 17-18
Dangerous section, beams, 8-08
Dardelet thread, 10-29
D-c motor control, 16-63 to 16-65 (*see also* Electric motor control)
D-c motors, 16-06 to 16-25, 16-51 to 16-55 (*see also* Electric motors)
  large power, 16-51 to 16-55
  small power, 16-20 to 16-25
Deactivation of water, 3-13
Dead loads, buildings, 27-07, (table) 27-05
Deaeration of water, 3-13
Decarburization, surface effect, 2-08
Decay, wood, 5-86
Decay resistance, wood, 5-81
Deceleration, 7-22
Decibel, 9-25
  scales (table), 9-26
Decimal equivalents, of fractions (table), 28-26, 28-52
Dedendum (def), 14-03
Deep drawing, 20-18, 20-29 (*see also* Drawing)
Deep-groove ball bearings, 12-67
  dimensions and radial capacities (table), 12-76
Defects, effect on endurance limit, 8-41
Deflection, angular, spiral spring, 11-26
  beams, 8-11
    due to shear, 8-11
  beams of uniform cross section (table), 8-12 to 8-14
  beams of uniform strength (table), 8-16
  Belleville springs, 11-32
  cantilever spring, 11-28
  flat plates, formulas (table), 8-32 to 8-35
  helical springs, 11-02, (table) 11-09 to 11-13
  leaf springs, 11-31
  shafting, 15-03
  statically loaded helical springs, chart, 11-15
  torsion springs, 11-24
  torsional, 8-29, 8-30
Deflection limit, beam, 8-15
DeForest scratch gage, 8-51
Deformability, bearing metals, 4-74
Deformation, torsional, formulas, 8-29, 8-30 (*see also* Deflection)
Degrees, decimals in minutes and seconds, 28-45
  equivalent in radians (table), 28-45
Density, metallic elements (table), 1-04
  metals (table), 6-02
  metric equivalents, 28-58
Deoxidized copper, 4-30, 4-31
Depth of cut (def), 23-05

Depth gage, 24-16
  micrometer, 24-19
Derivative control, 17-19
Derricks, 26-15 to 26-22
  guy, 26-16
  Jinniwink, 26-16
  safety standards, 26-15
  stiff-leg, 26-16
  tower, 26-17
Detent release coupling, 15-30
Deviation, servomechanism, 17-15
Dezincification (def), 3-18
  brass, 3-28
Dial indicator, 24-19
Diametral pitch (def), 14-05, (table) 14-09
Diamond, index of refraction, 27-69
  Mohs' hardness, 1-27
Diamond cutting tools, 23-25
Diamond pyramid hardness (def), 1-24
  conversion table, 1-25
Diamond wheels, grinding, 23-72
Diaspore clay, 5-47
Die blocks, 20-09
Die casting, aluminum, 19-37
  copper-base, 19-33
  magnesium, 4, 41, 19-38, 19-39
  zinc, 19-40
Die-casting alloys, 4-78 to 4-83
  aluminum-base, 4-81, 4-82
    physical properties (table), 4-82
  copper-base (brass), 4-83
  lead-base, 4-78
  magnesium-base, 4-82
    properties (table), 4-82
  tin-base, 4-78
  zinc-base, 4-62, 4-79 to 4-81
Die-sinking machines, 23-63
Die steels, 2-56
Dielectric heating, 22-25
Dielectric preheating, plastics molding, 25-50
Dies, combination, 20-32
  compound, 20-32
  drop forging, parting planes, 20-10
    wear tolerances (table), 20-12
  forging, 20-07 to 20-10
  hammer, 20-09
  hydraulic, 20-33
  impression, 20-09 to 20-10
  plastics molding, 25-55 to 25-58 (*see also* Plastics molds)
  progressive, 20-32
  rubber, 20-33, 20-38
  setting, 20-10
  stamping, characteristics and applications, 20-32, 20-33
  transfer, 20-33
  trimming, 20-33
  universal, 20-33
Diesel-electric locomotives, industrial, 26-58
Differential devices, servomechanisms, 17-15, 17-16
Differential pulley, 7-17
Differential screw, 7-10
Differentiation, numerical, 18-35
Diffraction, x-ray, 8-57
Digital calculators, 18-35
Dilectene, plastic, 5-40
Dilecto, plastic, 5-43
Dimensional stability, molded plastics, 5-33
  plastic sheeting, 5-32
Dimensioning, drawings, 24-02 to 24-07
  flat plywood, 25-21
Dimensions, specification of, 24-02 to 24-15
Dinking, 20-27
Diodes, 17-23
Direct current (def), 16-03
Direct-current motors, 16-06 to 16-25, 16-51 to 16-55 (*see also* Electric motors)
Direct-stress fatigue machine, 8-55
Directional effects, in metals, 1-21
  in steel, 2-04, (table) 2-05
Discharge coefficients, nozzles and orifices, 13-05
Disintegrators, dust collection, 27-97
Disk brakes, 17-41
Disk clutches, 15-31
Disk grinders, 23-90
Disks, rotating, 7-42, 7-43
Displacement, piston, formula and table, 7-04
  vibration, measuring instruments, 9-04 to 9-06
Displacement pickups, 8-52
Displacement-time diagrams, 7-22
  cam followers, 7-11, 7-12
Distortion-energy theory, 8-45
  equations, 8-46, 8-48
Dividers, 24-17
Division, by logarithms, 28-03
Dolomite, Mohs' hardness, 1-27
  specific gravity, 1-29
Double-block brake, 17-38
Double-end tenoners, 25-46
Double-enveloping gearing, 14-46
Double-row ball bearings, 12-67
  dimensions and radial capacities (table), 12-79, 12-80
Double-row cylindrical roller bearings, dimensions and radial capacities (table), 12-82
Douglas fir, 5-75, 5-84
Dowmetal, 4-41
Down-milling, 23-46, 23-57
Doyle scale, lumber, 25-03
Draft, pattern, 19-23
  tolerances for drop hammer forgings (table), 20-13
  tolerances for upset forgings (table), 20-13
Drafting standards, 24-02
Drag, flame cutting, 23-119
Drag link mechanism, 7-02, 7-03
Drag scrapers, 26-11
  storage system, 26-10
Dragline buckets, 26-13
Dragline crawler, 26-12
Dragline scraper, 26-11
Drain tile, 5-15
Draw-in cuts, grinding, 23-87
Drawing, conventional, 20-29
  furnaces for, 22-20
  magnesium, 4-48
  press, 20-18
  stretch, 20-30
  zinc, 4-64
Dressing, belt, 15-51
Drift bolts, resistance, 10-70
Drilling, 23-63 to 23-71
  cutting fluids for, 23-68
  feeds, 23-68
  plastics, 25-51
  speeds, 23-67, (table) 23-68
  thrust, torque and power for, 23-70
  tolerances, 24-06
Drills, 23-63 to 23-71
  for aluminum, 4-18
  for deep holes, 23-67
  failures, 23-69
  for interrupted holes, 23-67
  for magnesium, 4-45
  sharpening, 23-69
  special, 23-66
  tap, selection, 10-32

Drills (*continued*)
  twist, 23-63 to 23-67
    standard sizes (table), 23-64 to 23-66
Drip-proof motor (def), 16-18
Drives, adjustable-speed, electronic, 17-33
  belt, 15-44 to 15-67
  chain, 15-68 to 15-80
  hydraulic variable-speed, 15-90 to 15-95
  mechanical variable-speed, 15-85 to 15-90
  pivoted motor, 15-64 to 15-67
  rope, 15-80 to 15-82
  short-center belt, 15-64 to 15-67
  spring-tension motor base, 15-67
  V-belt, 15-53 to 15-63
  variable-speed, 15-84 to 15-96
  Ward Leonard, 17-33
Drop forging, 20-05 to 20-13 (*see also* Forging)
Drop forming, magnesium sheet, 4-48
Drop hammers, 20-05 (*see also* Hammers)
Drums, for wire rope, 6-11, 26-03
Dry measure, 28-55
Dry-sample borings, 27-55
Dryers, rotary, by-product recovery, 27-107
  spray, by-product recovery, 27-107
Drying, lumber, 25-14
  veneer, 25-12
Drying ovens, 22-17
Ductile fracture, 8-05
Ductile materials, working stresses, 8-46
Ductility (def), 8-04
  local, 2-03
  metals, 1-22
  tensile, 2-03
Dumbwaiters, buildings, 27-04
Dumpsters, 26-58
Duplex materials, 2-50
Duplicating, automatic, shapers, 23-45
Duralumin, corrosion, 3-29
  cutting fluid for, 23-19
Duranickel, 4-51 to 4-53
Durez, plastic, 5-41
Dust collection, 27-90 to 27-109 (*see also* Dust collectors)
Dust collectors, 27-93 to 27-99

  metallic elements (table), 1-04
Electrical speed control, 15-95, 15-96 (*see also* Electric motor control)
Electrodes, arc welding, 21-05
  carbon (table), 5-07
  current for welding steel (table), 21-05
  graphite (table), 5-08
  welding, 21-03
Electrogalvanizing, 3-11, 4-61
Electromagnetic clutches, 15-38
Electromagnetic spectrum, 27-64
Electromotive force series, 3-18, (table) 3-19
Electronic adjustable-speed drives, 17-33
Electronic comparator, 24-22
Electronic control, 17-23 to 17-37
Electronic timing, 17-32
Electronic tubes, amplification factor, 17-25
  transfer characteristic, 17-24
  types, 17-23 to 17-29
Electronic voltage regulators, 17-35
Electroplating, on aluminum, 4-21
  with nickel, 4-53
Electrostatic precipitators, 27-97, 27-98
  maintenance, 27-108
Elements, properties of metallic (table), 1-04
  symbols, atomic numbers and weights (table), 1-03
Elevating, 26-30 to 26-48 (*see also* Elevators)
Elevator bolts, 10-47
  dimensions (table), 10-48
Elevator furnace, 22-18
Elevator motors, single-speed, 16-38
Elevator rope, 6-16, (table) 6-16
Elevators, 27-04
  centrifugal discharge, 26-31
  miscellaneous materials, 26-35
  motors for, 16-38
  package, 26-46
  perfect-discharge, 26-33
  portable, 26-36
Ellipse, quadrant, center of gravity, 7-19
  section, area, moment of inertia, radius of gyration, 8-10
Ellipsoid, center of gravity, 7-19
  radius of gyration, 7-21
Elliptical gears, 7-03, 14-16
Elm, 5-75, 5-84
Elutriation, 27-91
Embossing, 20-31
Emery, specific gravity, 1-29
EMF series, 3-18, (table) 3-19
Emission, secondary, 17-25
Enamel (def), 3-09
Enameling irons, 2-39
Enclosures, for electric controls, 16-59
End coils, allowance for, in springs, 11-16
End conditions, column, 8-21
End-loaded beams, 8-19
End mills, 23-49
End quench hardenability testing, 2-20
End quench test curves, 2-21
Endless-bed sanders, 25-46
Ends, tension spring, 11-20
Endurance, 2-08 (*see also* Fatigue)
Endurance diagram, for helical springs, 11-06, 11-07
Endurance limit, determination, 8-41, 8-55
  effect of scratches and defects, 8-41
  gray cast iron, 19-05
Endurance loading, springs, 11-07, (def) 11-04
Endurance ratio, steel, 2-09
Energy, loss from impact, 7-27
  measure of, 7-24
  metric equivalents (table), 28-59
  required for forging, 20-02
Engine balance, reciprocating, 9-11
Engine lathe, 23-32
English system, rope drives, 15-81
English wire gage, 6-06
Epicyclic gear trains, 14-49
Equation solver, linear, 18-36
Equilateral polygon, area, moment of inertia, radius of gyration, 8-10
Equilibrium, beam, 8-07
Equilibrium diagrams, alloys, 1-07, 1-08
Erbium, 1-03
Error-measuring device, servomechanisms, 17-15
Escalators, buildings, 27-04
Ether, specific gravity, 1-29
Ethocel, plastic, 5-35
Ethyl alcohol, compressibility, 1-30
Ethyl cellulose, 5-34, 5-35
Ethyl ether, compressibility, 1-30
Ethylene, compressibility, 1-31
Euler's formula, columns, 8-22
Europium, 1-03
Eutectic, 1-08
  principal alloys (table), 1-09
Everdur, 4-36, 4-37
Evergreen magnolia, 5-79
Exciter (def), 16-03
Exhaust hoods, overhead, safety, 27-81
Exhaust systems, central, 27-100
  unit, 27-105
Exits, safety, 27-80
Expansion coefficient, 1-04 (*see also* Thermal expansion)
Expansion fits, 24-14
Expansion joints, buildings, 27-19
Experimental stress analysis, 8-48, 8-52
Explosion muffler, 9-33
Explosionproof motor (def), 16-19
Explosive dusts, 27-92
Exponential equations, solution by logarithms, 28-04
Exponential functions, (table) 28-24
Extinguishers, fire, portable, 27-89
Extra-fine-thread series, 10-09 (*see also* Screw threads)
Extreme-pressure packing, 18-07
Extruded architectural bronze, 4-32, 4-33
Extruding, 20-08, 20-31
Extrusion molding, 25-53
Extrusions, magnesium, 4-42
  surface roughness, 24-31
  zinc, 4-64

General Motors strain gage, 8-50
General-purpose motors, 16-51, 16-52 (*see also* Electric motors)
Generating, bevel gear teeth, 23-115
  gear teeth, 23-113
Generator, electric (def), 16-03
Generators, motors for, 16-56
Geneva stop, 7-06
Geneva wheel, 7-06
Geon, plastic, 5-35
Germanium, 1-03, 1-04, 4-69
  compressibility, 1-31
Gib-head keys (table), 15-10
Gilding metal, 4-30, 4-31
Girders, buildings, 27-17
  wood, for roofs, 27-32
Glass, 5-25 to 5-31, (def) 5-25
  adhesives for, 21-30
  chemical nature, 5-25
  chemical properties, 5-26 to 5-29
  corrugated wire, 27-36
  crown, index of refraction, 27-69
  electrical properties, 5-29
  flint, index of refraction, 27-69
  forming methods, 5-30
  grinding wheels for, 23-79, 23-80
  light transmitted, 27-68
  mechanical properties, 5-28
  mirrored, light reflected from, 27-68
  Mohs' hardness, 1-27
  physical properties, 5-26 to 5-29, (table) 5-27
  plate, compressibility, 1-31
  specific gravity, 1-29
  thermal properties, 5-28
  types, 5-25
Glass block, walls, 27-46
Globoid worm drives, 14-46
Glue joints, testing, 21-25
Glue spreaders, 25-21
Glue testing, 21-24
Glues, 21-20 to 21-30
  animal, 21-21
  blood albumin, 21-22
  bone, 21-21
  casein, 21-22
  casein latex, 21-30
  dried blood, 21-22
  fish, 21-21
  hide, 21-21
  primary, 21-20
  secondary, 21-20
  silicate of soda, 21-23
  soybean, 21-23
  vegetable, 21-24
Gluing, plywood, 25-17 to 25-27
  layout, 25-20
Glycerol, compressibility, 1-30
  specific gravity, 1-29
Gneiss, specific gravity, 1-29
Gold, 1-03, 1-04, 4-69
  compressibility, 1-31
  Mohs' hardness, 1-27
  plastic properties, 20-23
Goodman relation, 8-48
Government babbitt, machinability, 23-15
Grab buckets, 26-12
Grab hook, 26-07
Grab link, 26-07
Grade, grinding wheels, 23-72
Graham variable-speed transmission, 15-89
Grain, conveying, 27-102
  unloading, 27-106
Grain depth of cut, grinding, 23-86
Grain size, abrasives, 23-71
Grain size (*continued*)
  metals, 1-06
Grain unloading, 26-44
Grains, boundaries, 1-12
  crystal, 1-06
Granite, grinding wheels for, 23-80
  specific gravity, 1-29
Granular friction, 7-30
Graphite, 5-02 to 5-09
  carbon, specific heat, 5-02, 5-03
  compressibility, 1-31
  Mohs' hardness, 1-27
  physical characteristics (table), 5-04
  specific gravity, 1-29
Graphite electrodes (table), 5-08
Graphitic steels, 2-47
Graphitization, malleable iron, 19-13
Grates, 22-09
Gravel (def), 27-54
  specific gravity, 1-29
Gravitation, law, 7-25
Gravitational motion, 7-12
Gravity, acceleration due to, 7-23, 7-25
  center of, 7-18, 7-19
Gravity idler drive, 15-63
Gray iron, 2-31, 19-02 to 19-14 (*see also* Cast iron)
Grease lubrication, rolling bearings, 12-71
Greases, 12-62
Greek letters, 28-60
Green wood, 5-89
Greenheart, 5-81
Greenstone, specific gravity, 1-29
Grid, electronic tubes, 17-24
  screen, 17-25
  suppressor, 17-26
Grinders, by-product recovery, 27-107
  cam, 23-91

    planing, 23-39
    sawing, 23-108
    shaping, 23-43
    turning, 23-31
  motors for, 16-56
  for wood, 25-39 to 25-47
Machinery, foundation vibrations, 9-17
Machines, automatic screw, 23-34
Machining, allowance, forgings, 20-14
  aluminum alloys, 4-18
  magnesium alloys, 4-43
  zinc, 4-65
Magnaflux, 8-58
Magnaglo, 8-58
Magnesia, carbonate, specific gravity, 1-29
Magnesite, specific gravity, 1-29
Magnesite brick, 5-48 to 5-56
Magnesite-chrome brick, 5-48, 5-52, 5-56
Magnesium, 1-03, 1-04, 4-40 to 4-50
  alloys of, 1-09, 4-40 to 4-50 (*see also* Magnesium alloys)
  castings, 4-41
  compressibility, 1-31
  corrosion resistance, 3-29, 3-30
  die castings, 4-41
  drills for, 23-66
  extrusions, 4-42
    mechanical properties (table), 4-43
  forged parts, 4-42
  grinding wheels for, 23-80
  handling, 4-45
  joining, 4-46 to 4-48
Magnesium (*continued*)
  plate, sheet, and strip, mechanical properties, 4-43
  protective treatments, 4-49
  surface finishing, 4-49
Magnesium alloys, 1-09, 4-40 to 4-50
  casting, 19-38, (table) 4-42
  composition (table), 4-41
  corrosion resistance, 3-29, 3-30
  die-casting, 4-82
    properties (table), 4-82
  joining, 4-46 to 4-48
  physical constants, 4-41
Magnesium carbonate, light reflected from, 27-68
Magnesium oxychloride, grinding wheel bond, 23-72
Magnetic analysis inspection, 8-58
Magnetic chucks, 23-42
Magnetic clutches, 15-34
Magnetic controller (def), 16-03
Magnetic gages, 18-27
Magnetic-particle inspection, 8-58
Magnetic strain gage, 8-49, 8-50
Magnetite, Mohs' hardness, 1-27
Magnets, lifting, 26-14
  lifting capacity (table), 26-14
Magnolia, 5-77
Mahogany, 5-81
Malleability (def), 8-04
Malleable anneal, 19-28
Malleable castings, grinding wheels for, 23-81
  properties and design, 19-29 to 19-31
  specifications, 19-29
Malleable iron, 2-33, (def) 19-26
  alloy, 2-33, 19-31
  casting production, 19-27 to 19-29
  composition, 19-27
  cupola, 2-33
  cutting fluid for, 23-19
  machinability, 19-29
  metallurgical structure, 19-26
  pearlitic, 19-31
  physical and mechanical properties (table), 19-29
  specification, 2-33
  uses, 19-26
Manganese, 1-03, 1-04, 4-69
  compressibility, 1-31
Manganese bronze, 4-27, 4-32, 4-33
  specifications, 4-28
Manganin, 4-70
Manifold circuit, hydraulic, 13-07
Manila rope, 6-20
  weight and strength (table), 6-21
Manila-rope drives, 15-80 to 15-82
Manila-rope hoisting, 26-02
Maple, 5-77, 5-84
Marble, grinding wheels for, 23-81
  Mohs' hardness, 1-27
  specific gravity, 1-29
Marblette, plastic, 5-42
Marine bronze, machinability, 23-15
Marline-clad rope, 6-16, (table) 6-16
Martensite, 2-12
Martensitic stainless steels, 3-22, (table) 3-20
Masonry, brick, 27-44
    compressive stresses (table), 27-45
  hollow, 27-46
  specific gravity, 1-29
  stone, compressive stresses (table), 27-45
  walls, 27-42
Mass, metric equivalents (table), 28-57
Mat foundations, 27-58

Matched veneer, 25-18
Matches, hazards, 27-88
Materials, bulk, feeding, 27-106
    separation, 27-107
  spring, 11-35 to 11-40
    composition of (table), 11-35
Materials handling, safety provisions, 27-86
Mathematical signs and abbreviations, 28-60
Mathematical tables, 28-03 to 28-59
Matrix alloy, 4-68
Maximum-shear theory, 8-45
Maximum-strain theory, 8-44
Maximum-stress theory, 8-44
Measurement, angles, 24-23
  high-precision, 24-19 to 24-23
  machine performance, 18-22 to 18-31
  nonprecision, 24-16
  power, 18-26, 18-28 to 18-31
  precision, 24-17
  pressure, 18-26
  screw threads, 24-24
  space-time, 18-26, 18-27
  speed, 18-27
  torque, 18-26, 18-28 to 18-31
Measures and weights, 28-55
Measuring machines, 24-19, 24-20
Mechanical adhesion, 21-20
Mechanical equipment, buildings, 27-13
Mechanical presses, 20-08, 20-34 (*see also* Presses)
Mechanism (def), 7-02
Medium fits, 24-08, (table) 24-09
Medium force fits, 24-10, (table) 24-12
  stresses and forces, 24-13
Meerschaum, Mohs' hardness, 1-27
Melamine formaldehyde, 5-41, 5-42
Melamine formaldehyde adhesives, 21-24
Melmac, plastic, 5-42
Melting, aluminum alloys, 19-36
  cast iron, 19-06
  copper-base alloys, 19-35
  energy required for, 22-23
  furnaces for, 22-23
  magnesium alloys, 19-38
  malleable iron, 19-27
  steel, 19-17
Melting temperature, glass, 5-28
  metallic elements (table), 1-04
Mercury, 1-03, 1-05, 4-70
  compressibility, 1-30
Mercury vapor lamps (table), 27-74
Metal arc welding, 21-04
Metal-mold casting, 19-25, 19-33, 19-37 to 19-39 (*see also* Permanent-mold casting)
Metal removal by cutting tools, rate, 23-20 to 23-22
Metal sawing, 23-108 to 23-112
Metal spraying, zinc coatings, 4-61
Metal-to-metal adhesives, 21-29
Metal-to-wood adhesives, 21-29
Metal turnings, conveying, 27-102
Metallic elements, properties (table), 1-04
Metallizing, 3-12
Metallography, 1-02 to 1-08
  zinc, 4-65
Metalloids, 1-02
Metallurgical principles, strengthening steel, 2-15 to 2-30
Metallurgy, iron and steel, 2-10 to 2-15
Metals, adhesives for, 21-27
  allotropic forms, 1-07
  alloying properties, 1-08 to 1-10
  antifriction, 7-31
  classification, 1-02

  for underwater service, 3-09
  white, light reflected from, 27-68
Painting, of aluminum, 4-21
  of magnesium, 4-49
  preparation of metal surface for, 3-09
  of zinc, 4-67
Palladium, 1-03, 1-05, 4-70
  compressibility, 1-31
  Mohs' hardness, 1-27
Pallets, 26-49, 26-50
Panelyte, plastic, 5-43
Pantograph, 7-06
Paper, specific gravity, 1-29
  white blotting, light reflected from, 27-68
Paper products, glues and adhesives for, 21-25 to 21-27
Paper pulleys, 15-41
Papreg, 5-82, 25-26
Parabolic motion, 7-12
Parabolic surface, center of gravity, 7-19
Paraboloid, center of gravity, 7-19
  radius of gyration, 7-21
Paraffin, specific gravity, 1-29
Parallel keys (tables), 15-08, 15-10
Parallelogram, center of gravity, 7-19
Parallelopiped, radius of gyration, 7-21
Parana pine, 5-80
Parapet walls, 27-49
Paraplex, plastic, 5-38
Parging, 27-43, 27-44
Parkerizing, 3-10
Parting, 20-26, (def) 3-18
Partitions, 27-51
  fire-resistive periods (table), 27-09
  masonry, minimum thickness (table), 27-51
Passivator (def), 3-05
Pawl, 7-07
Pearlite, 2-11
Pearlitic malleable iron, 2-34, 19-31
  specification, 2-34
Pearlitic steels, high-temperature, 2-52
Peat, specific gravity, 1-29
Pecan, 5-76
Pedestal mounting, bearing, 12-42
Peening, bearing faces, 12-48
  shot, 20-40 to 20-49 (*see also* Shot peening)
Pendulum, 7-26
Pentodes, 17-26
Perception of sound, 9-24
Percussion, center of, 7-27
Percussive welding, 21-03
Perforating, 20-26
Performance testing, machines, 18-22 to 18-31
Periodic classification, metallic elements (table), 1-04
Peripheral milling, 23-46
Permanent-mold casting, aluminum alloys, 4-04, 19-37
  copper alloys, 19-33
  iron and steel, 19-25
  magnesium alloys, 4-41, 19-38
  zinc alloys, 19-39
Permeability, rubber, 5-59
Peters strain gage, 8-51
Pewter, cutting fluid for, 23-19
Phanotrons, 17-24
Phase, electric power, 16-11
Phase-wound amortisseur windings, 16-47
Phenol formaldehyde, 5-41
Phenol formaldehyde adhesives, 21-23
Phenolics, cast, 5-42
  laminated, 5-43
  molded, 5-41
Phenolite, plastic, 5-43
Phosphate coatings, 3-10
Phosphate rock, specific gravity, 1-29
Phosphor bronze, 4-32 to 4-35
  machinability, 23-15
  Mohs' hardness, 1-27
  for springs, 11-36, 11-39
Phosphorus, 1-03, 1-05
  compressibility, 1-31
  in steel, 2-11
Photoelastic strain measurement, 8-52
Photoelasticity, 8-51
Photoelectric devices, 17-28
Photoelectric emission, 17-23
Photoelectric pyrometry, 18-34
Photoelectric register regulator, 17-36
Photoelectric relays, 17-32
Photoelectric scanner, 17-36
Photogrid, strain measurement, 8-51, 8-52
Phototubes, 17-28
Photovoltaic cells, 17-29
Pickling tanks, materials for, 3-24
Piercing, 20-26
Piers, 27-49
  concrete, 27-63
  footings for, 27-56
Pig iron, 2-02
Pignut, 5-77
Pile driving, 27-60, 27-62 (*see also* Piles)
Piles, concrete, 27-60
  metal pipe, 27-61
  structural-steel, 27-61
  wood, 27-60
Pillar crane, 26-15
Pillar jib crane, 26-15
Pillow block, with circulating oil, 12-72
Pin joints, 18-17
Pin keys, 15-13
Pine, 5-78, 5-79, 5-84
Pins, knuckle joint, SAE standard, 18-17, 18-18
  shear, 15-29

Pipe threads, torque for tapping, 23-30
Pipes, dust collector systems, gages of metal, 27-104
  round, entry losses for, 27-103
Piping, dust collector systems, design, 27-101
    maintenance, 27-108
  gas, buildings, 27-04
  hydraulic, 13-17
  identification, for safety, 27-81
  pressure loss, 13-02, 13-03
Piston, displacement, formula and table, 7-04
  inertia force, 7-37
  linear acceleration, formula, 7-05, (table) 7-38
  linear velocity, formula, 7-04, (table) 7-36
Piston motors, hydraulic, 13-11
Piston pumps, 13-08
Piston rings, 18-13
Piston valves, hydraulic, 13-13
Pit furnace, 22-18
Pitch, specific gravity, 1-29
Pitch diameter, fine-pitch worms (table), 14-58, 14-59
  gears (def), 14-03
  screw, formula, 10-06
Pitting (def), 3-18
  stainless steels, 3-23
P.I.V. gear, 15-85
Pivoted motor drives, 15-64 to 15-67
Pivoted shoe bearings, 12-31 to 12-40 (*see also* Bearings, pivoted shoe)
Place bolt, 10-54
Plane bending fatigue machine, 8-55
Plane figures, center of gravity, 7-19
  radius of oscillation (table), 7-26
Planer tools, for machining aluminum, 4-18
Planer work, 23-38 to 23-43
Planers, cabinet, 25-42
  developments, 23-42
  guarding, 27-85
  load-carrying capacity, 23-40
  speeds and feeds, 23-41, 23-42
  table speeds, 23-42
  tools for, 23-40
  types and sizes, 23-39, 23-40
  woodworking, 25-36, 25-40, 25-42
    cutting angles and knife cuts per inch (table), 25-41
Planet pinions, equal spacing, 14-52
Planetary gear trains, 14-49
Planetary gears, compound, 14-50
  ratio limitations, 14-52
Planetary milling machines, 23-63
Planimeter, 18-36
Planing, power required for, 23-39
  time for, 23-42
  tolerances, 24-06
Planing mill, exhaust system, 27-100
Planished iron, 3-10
Plank, cement-aggregate, 27-50
Plaskon, plastic, 5-42
Plastacele, plastic, 5-34
Plaster, white, light reflected from, 27-68
Plaster-mold casting, copper alloys, 19-33
Plaster-of-Paris, specific gravity, 1-29
Plastic laminates, high-pressure, 5-42
Plastic properties, aluminum alloys, 20-22
  metals (table), 20-23
Plasticity (def), 8-03
  metals, 1-11
Plasticizers, 5-33
Plastics, 5-31 to 5-46
  grinding wheels for, 23-82
  laminated, 5-42 to 5-45, 25-53 to 25-55
  molded, drill for, 23-67
Plastics (*continued*)
  production (table), 5-44
  thermoplastic, 5-34 to 5-41
  thermosetting, 5-41, 5-42
  trade names, 5-45
Plastics molded parts, design, 25-58 to 25-61
  tolerances, 25-61, 25-62
Plastics molding, 25-47 to 25-62
  extrusion, 25-53
  transfer, 25-48
Plastics molds, cavity design, 25-56, 25-57
  classes, 25-49
  design, 25-55
  flash type cavity, 25-57
  injection, 25-56
Plastilock, adhesive, 21-28
Plate glass, compressibility, 1-31
Plates, flat, stress and deflection formulas (table), 8-32 to 8-35
  thin circular, radius of gyration, 7-21
  weight (table), 6-02
Platform trucks, 26-52
Plating, on aluminum, 4-21
  with nickel, 4-53
  on zinc, 4-67
Platinum, 1-03, 1-05, 4-70
  alloys, 1-10
  compressibility, 1-31
  Mohs' hardness, 1-27
Plat-iridium, Mohs' hardness, 1-27
Plenums, entry losses, 27-104
Plexene M, plastic, 5-38
Plexiglas, plastic, 5-36
Pliotrons, 17-24
Plow bolts, 10-48
  dimensions (table), 10-48
Plow steel, soft center, 2-50
Plow steel wire, strength, 6-09
Plug cutter, 25-38
Plug gages, 24-26
Plug valves, hydraulic, 13-13
Plugging, motors, 16-09
Plumbing, buildings, 27-04
Plunger type transfer molding, 25-48
Plutonium, 1-03
Plymetal, 21-29, 25-26
Plywood, 5-82, 25-17 to 25-27
  curved, 25-21 to 25-23
  design, 5-86, (table) 5-87
  flexible, 25-24
  formed, 25-24
  modified, 25-26
  operations, general arrangement, chart, 25-18
Pneumatic conveying, 26-43, 27-105
Point follower, cam, 7-13
Poisson's ratio (def), 8-03
  steel, 2-57
Polar moment of inertia, 7-20, 8-28
Polar radius of gyration, 8-28
Polariscope, 8-52
Polarization, light, 27-69
Polaroid, 27-69
Polishing, 23-96
  machinery, 23-100
  plastics, 25-51
Polonium, 1-03
Polyester cast plastics, 5-38
Polyethylene, 5-38, (table) 5-37
Polygon, equilateral, area, moment of inertia, radius of gyration, formulas, 8-10
Polymeric amides, synthetic, 5-39
Polystyrene, 5-37, (table) 5-37
Polytetrafluorethylene, 5-39
Polythene, plastic, 5-38

Polyvinyl acetate, 5-35
Polyvinyl alcohol, 5-36
Polyvinyl butyral, 5-36
Polyvinyl chloride, 5-35
Polyvinyl chloride acetate, 5-36
Polyvinylidene chloride, 5-36
Poplar, 5-79, 5-84
Porcelain, dry-process, 5-11
  electrical, 5-11 to 5-14
  grinding wheels for, 23-82
  properties (table), 5-12
  specific gravity, 1-29
  wet-process, 5-11
    dielectric strength, 5-14
Porcelain enamel, light reflected from, 27-68
Porcelain enameling, furnaces for, 22-20
Porosity, refractory brick, 5-53, (table) 5-54
Porous carbon, 5-05, (table) 5-06
Porous graphite, 5-05, (table) 5-06
Porous products, ferrous, 2-57
Porphyry, specific gravity, 1-29
Portal cranes, 26-19
Porter-Lipp strain gage, 8-51
Portland cement coatings, 3-16
Ports, for furnaces, 22-06
Positive-engagement clutches, 15-35
Post-forming laminated phenolic plastics, 5-43
Pot furnaces, 22-14, 22-18
Potassium, 1-03, 1-05
  compressibility, 1-31
Potassium chloride, compressibility, 1-31
Powder iron, 2-57
Powder metal parts, design, 19-48
Powder metallurgy, 19-45 to 19-50, (def) 19-45
  economic aspects, 19-47
  process, 19-46
Powdered coal, for industrial heating, 22-07
Power, metric equivalents (table), 28-59
  to raise a number to a, 28-03
Power amplifier, electronic, 17-31
Power factor (def), 16-05, 16-13
Power measurement, 18-26, 18-28 to 18-31
Power screws, 7-08 to 7-11, 10-02 to 10-04
Power shovel, 26-12
Power supply, electric motors, 16-10
Power transmission, belting, 15-44
  shafting, 15-03
  wire rope, 15-82
Praseodymium, 1-03
Pratt truss, 27-29
Precipitate-hardening alloy systems (table), 1-15
Precipitation-hardened ferritic steel, 2-55
Precipitation hardening, 2-16
Precipitation heat treatment, aluminum alloys, 4-17
Precipitators, electrostatic, 27-97, 27-98
Precision gage blocks, 24-21
Precision investment casting, 19-40 to 19-45
  iron and steel, 19-25
  materials for, 19-41
Precision measuring devices, 24-17
Prefabrication, buildings, 27-20, 27-21
Preferred sizes, 24-08
Preforming, equipment, plastics molding, 25-49
Pregwood, 25-26
Preheating, thermosetting materials, 25-50
Preservation, wood, 25-28 to 25-31
Preservative oils, for wood, 25-28
Presetting, springs, 11-03
Presses, automatic, 20-35
  C-frame, 20-34
  forging, 20-05
  gap, 20-34
Presses (*continued*)
  guarding, 27-85
  hydraulic, 20-08, 20-33
  knuckle-joint, 20-35
  mechanical, 20-08, 20-34
  percussion, 20-08
  stamping, selection, 20-33 to 20-37
Pressure, metric equivalents (table), 28-59
  riveting, 10-61
Pressure angle, gears (def), 14-04
Pressure-control valves, 13-15, 13-16
Pressure indicators, 13-18
Pressure loss, in pipes, 13-02
Pressure measurement, 18-26
Pressure-reducing valves, 13-17
Pressure-regulating valves, 13-15
Pressure seals, 18-02 to 18-15
Pressure-velocity experience chart, bearings, 12-49
Pressure vessels, safety, 27-81
Prestressing, screws, 10-55
  by shot peening, 20-41
Primavera, 5-81
Prime movers, guards for, 27-82
Principal stresses, determination, 8-43, 8-44
Prism, center of gravity, 7-19
  moment of inertia, 7-20
  rectangular, radius of gyration, 7-21
Process control, 17-13
Process quality, 24-36
Producer gas, for industrial heating, 22-07
Production milling, 23-60
Profile cutters, milling, 23-48
Profiling machines, milling, 23-63
Projection equipment, motion picture, 18-24
Prony brake, 18-29
Proof coil, chain, 6-22, 6-23
Proof test, chain (table), 6-23
Propeller unbalance, airplane, 9-11
Proportional limit (def), 8-03
Protected motor (def), 16-18
Protection, eye, 27-87, 27-88
  foot and leg, 27-88
  hand, 27-88
  head, 27-88
  time-delay undervoltage, 16-59
Protective treatments, magnesium, 4-49
Protoactinium, 1-03
Protractor, universal bevel, 24-23, 24-24
Prystal, plastic, 5-42
Pullers, car, 26-29
Pulley blocks, 7-16
Pulleys, 15-39 to 15-43
  cast iron, 15-39, 15-40
  cone, 15-43
  conveyor, 15-41
  differential, 7-17
  guide, 15-52
  idler, 15-52
  nonmetallic, 15-41
  relative horsepower capacity, 15-42
  steel, 15-40, 15-41
  variable-pitch, 15-86
Pulp chips, conveying, 27-102
Pulverizers, by-product recovery, 27-107
Pumice, specific gravity, 1-29
Pumps, axial piston, 13-08
  gear, 13-08
  hydraulic, 13-08 to 13-10
  motors for, 16-57
  piston, 13-08
  vane, 13-09
Punched card machines, 18-36
Punches, 20-08, 20-16

Variable-pitch belt pulleys, 15-86
Variable-ratio rolling contact drives, 15-89
Variable-speed drives, 15-84 to 15-96 (*see also* Transmissions, variable-speed)
Variable voltage control, 16-55
Vari-Drive, 15-87
Variety saw tables, 25-39
Vari-Pitch drive, 15-87
Vari-Speed pulley, 15-87
Varnish (def), 3-09
  for wood, 25-27
Vascoloy-Ramet, cemented carbide, 23-23
V-belt drives, 15-53 to 15-63
  center distance, 15-61
  horsepower (tables), 15-55 to 15-59
  selection, 15-60
  service factors (table), 15-60
V-belt sheaves, face width (table), 15-62
  sizes, 15-61
V-belts, standard, 15-54, (table) 15-54
V-bucket carrier, 26-33
Vee packings, 18-08
Vegetable glues, 21-24
Vehicle suspension, 9-22
Vehicles, materials handling, 26-49 to 26-60
Velocity (def), 7-21
  angular (def), 7-22
  cam followers, 7-12
  crank mechanism (table), 7-36
  linear, of point on turning body, 7-22
  linkages, 7-07
  metric equivalents (table), 28-58
  piston, formula, 7-04
  slider-crank mechanism, 7-08
  sound, 9-24
Velocity detector, 9-06
Velocity factors, gear tooth design, chart, 14-26
Velocity pickups, 8-52
Velocity polygon, 7-07
Velocity-time diagram, 7-22
Veneer, 25-06 to 25-08
  book-matched, 25-17
  dimensioned, 25-18
  face, 25-17
  half-round, 25-07, 25-12
  matched, 25-18

WILEY ENGINEERING HANDBOOK SERIES

HANDBOOK OF ENGINEERING FUNDAMENTALS. Edited by Ovid W. Eshbach.

KENT'S MECHANICAL ENGINEERS' HANDBOOK. Twelfth Edition.

DESIGN AND PRODUCTION. Edited by Colin Carmichael.

POWER. Edited by J. K. Salisbury.

ELECTRICAL ENGINEERS' HANDBOOK. Fourth Edition.

ELECTRIC POWER. Edited by Harold Pender and William A. Del Mar.

ELECTRIC COMMUNICATION AND ELECTRONICS. Edited by Harold Pender and Knox McIlwain.

MINING ENGINEERS' HANDBOOK. Third Edition. Edited by the late Robert Peele.

HANDBOOK OF MINERAL DRESSING.

ORES AND INDUSTRIAL MINERALS. Edited by Arthur F. Taggart.
